## DISSERTATION

Presented to the Graduate Council
of Texas State University-San Marcos
in Partial Fulfillment
of the Requirements
for the Degree
Doctor of Philosophy
by

Rebecca K. Parylak, B.A., M.A.Geo.

San Marcos, Texas
May 2010

# THE SPATIAL AND TEMPORAL TRENDS IN PRECIPITATION IN TEXAS 

Committee Members Approved:

Richard W. Dixon, Chair

David R. Butler

Philip W. Suckling

Philip L. Chaney

Approved:
J. Michael Willoughby

Dean of the Graduate College

## ACKNOWLEDGEMENTS

I would like to acknowledge the many colleagues, mentors, and friends who have contributed and supported me throughout my time in graduate school. First and foremost, I would like to thank my advisor, Rich Dixon for his unlimited patience, his warm approach to supervision, and supporting me, especially as I struggled with personal challenges during the latter half of my graduate school experience. Thank you for both your personal and academic advice, and for believing in me and in my ability to improve myself through perseverance and hard work. I will continue to persist and work hard as I begin my professional life in academia. I would also like to extend my thanks to the other members of my committee, David Butler, Phil Suckling, and Phil Chaney for their time and feedback throughout my time in graduate school and for this project. I want to thank Allison Glass, Angelika Wahl, Charles Robinson, and Judy Behrens for your assistance, service, and support.

A number of friends were extremely encouraging and helpful throughout my graduate school years, and made a lasting impact on my personal and professional life. I want to thank James Vaughan, Dawna Cerney, Carol Sawyer, Fenda Akiwumi, Darlene Occena-Guiterrez, Mindy Conyers, Jamie Zech, David Viertel, Jay Parsons, Brian and Alecia Brettschneider, and many others that I worked with in the department and attended classes with for their support and friendship. It was a privilege to work with you and I am truly blessed to know you and for your continued friendship. Finally, to Emariana Taylor and Melissa Gray, thank you for your friendship, love, and support. The three of
us have been through quite a journey together during and after our graduate studies. I will always cherish our times, especially those on the Comal River, and also our move from Texas to Ohio. You both have definitely made my life much richer. Thank you.

A very special thanks goes to Nicola Harlan, who I can say is my best friend for over a quarter of a century. Nik, as you go through graduate school yourself in the coming years, I only hope to be there for you as you have been for me. I also extend a heartfelt thanks to Dona and Mike Eggenberger, Cari Eggenberger, Sharon Jimenez, Don and Cheri Dancak, Tom and Romy Cisneros, Elena and Richard Luderus, who supported and encouraged me throughout my educational venture. A special thanks goes to Panos Zavos who gave me valuable advice and insight to his graduate studies experience and successful career. I also like to acknowledge and thank my colleagues at Kent State University for their continued support.

Mom and Dad, I thank you both for your unconditional love and continued support throughout my time in graduate school. I love you both and I appreciate the sacrifices you have made to help me accomplish my goals while in graduate school and with my move to Ohio. I am proud to be your daughter. To my sister, Debra and husband, Mike, thank you for your continued love and support. Finally, to my son Jonathan, who stood by me all these years and took the journey to Ohio with me to begin new experiences and a new life. I am very proud of you and I am extremely grateful for your love and support.

#### Abstract

THE SPATIAL AND TEMPORAL PATTERNS OF PRECIPITATION IN TEXAS

by<br>Rebecca K. Parylak

Texas State University-San Marcos

SUPERVISING PROFESSOR: RICHARD W. DIXON

Water sustains our cities, rural communities, businesses, industries, farms, ranches, and the natural environment. Any disruption to our water supply will significantly affect the economy and human life (Kursinski 2007). Water is an important, limited resource and any change in the hydrological cycle might result in an increase in flood or drought conditions (Kursinski 2007). Texas agricultural economies have adapted to precipitation regimes; however, they are vulnerable to precipitation anomalies, especially those that last more than one month (Lyons 1990). An analysis of 42 stations of annual and seasonal precipitation from 1932-2002 for the state of Texas is presented. Annual and seasonal total precipitation, precipitation days, and precipitation intensity are investigated using a linear regression model. Regression results reveal positive trends in annual precipitation, days with precipitation, and precipitation intensity for the southeast region. During the spring and summer months, an increase in precipitation intensity resulted for stations in the north central region, while the most notable trend during the
fall months showed an increase in precipitation in the eastern half of the state, while no change resulted in the west. A decrease in precipitation days was noted for stations in south Texas, with no change in intensity or total precipitation.

## CHAPTER 1

## INTRODUCTION

## Statement of Research Problem

Precipitation is an important weather and climate element that has a significant impact on society (Kursinski 2007). Water is a vital resource for human life and is central to many national concerns including economic health and development, food security, and environmental quality (Dzurik 1996). Water sustains our cities, rural communities, businesses, industries, farms, ranches, and the natural environment, and any interruption to our water supply will adversely affect the economy and human life (Pittman et al. 2007).

From a societal perspective, water is a precious, limited resource and any change in the hydrological cycle might result in an increase in floods or droughts (Kursinski 2007). Texas agricultural economies have adapted to precipitation regimes; however, they are vulnerable to precipitation anomalies, especially those that last more than one month (Lyons 1990). This vulnerability has been studied and statistics show that the central United States from North Dakota to southern Texas is most likely to experience periods of drought or wet spells (Lyons 1990). Historically, periods of drought in Texas are well documented. Jensen (1996) notes that some of the earliest droughts include one in the $15^{\text {th }}$ century along the Canadian River that decimated a native American tribe. Furthermore, a drought event in 1756 dried up the San Gabriel River, and the drought of

1822 caused crops planted by Stephen F. Austin to perish. Jensen (1996) states that at least one drought has affected Texas each decade from 1822 through the $20^{\text {th }}$ century. The best two examples include the drought of the 1930s, and the drought of the early to mid-1950s. The drought of the 1930s seemed to be the worst drought inflicted upon Texas; however the statewide drought during the 1950s resulted in 244 of Texas’ 254 counties being declared disaster areas (Ward 2000; Pittman et al. 2007). The drought in the 1950s lasted nine years and caused considerable stress to farmers, livestock, and to the public (Ward 2000). Quentin Martin, from the Lower Colorado River Authority (LCRA), examined tree-ring data and hydrologic data of the last 200 years to assess drought conditions that impacted Central Texas (Ward 2000). His findings imply that the drought of the 1950s was the worst in terms of intensity and magnitude. This drought was believed to begin in the Lower Rio Grande Valley and West Texas in 1949, with precipitation dropping by 40 percent from 1949 to 1951 , and by 1952, half the state received 20 to 30 inches less rainfall than normal (Ward 2000). Average monthly precipitation in 1952 fell to 0.03 inches and is considered the lowest level since the Weather Bureau began collecting records in 1888 (Jensen 1996).

Texas is rapidly growing in population and future water demands could easily exceed the available water supplies. A major source of domestic water supply in Texas, especially in the early twentieth century was groundwater (aquifers); however during the twentieth century, the demand for water exceeded the aquifer yield and surface water supplies were sought (Ward 2000). The state water plan involves 16 regional water planning groups that represents a geographic region in Texas based on hydrologic and political borders (Pittman et al. 2007). The water planning groups review water use
projections, implement management strategies in times of drought conditions, and recommend a management strategy when a water need is identified (Pittman et al. 2007). The population in Texas is projected to more than double by year 2060, to approximately 46 million. Pittman et al. (2007) state that if Texas does not implement the state water plan, about 85 percent of the state's projected population will not have enough water by 2060 during drought conditions. With this in mind, it is essential to investigate the changes in temporal and spatial precipitation patterns in Texas in order to improve domestic water supply management strategies (Harmel et al. 2003).

Using historical precipitation data, this research examines the spatial and temporal patterns of precipitation in Texas. The central goal of this research is to identify trends in monthly, annual, and seasonal precipitation for 42 weather stations in Texas, and to determine if areas around the state are becoming increasingly wet or dry. The results of this study will contribute to the understanding of precipitation patterns in Texas and will aid in making informed decisions and predictions as far as future water supplies are concerned for the state. In addition, the results of this study will be important to a large segment of the climatological, hydrologic, and atmospheric science communities. Further, variations in precipitation on a spatial and/or temporal scale may provide insight into precipitation behavior as an indicator of climate change.

## Research Objectives and Hypotheses

Precipitation is one of the drivers of variability in the atmospheric water balance, and any change in precipitation for a location will have a significant impact on water resources for the state (Brommer 2006). Additionally, changes or modifications in the hydrologic cycle may either result in an increase in floods or drought conditions.

Findings from this study will contribute to the understanding of the spatial and temporal patterns of precipitation in Texas. Therefore, understanding variations and historical patterns of precipitation will aid in water resource management, drought mitigation, and community planning for the state.

The primary purpose of this dissertation is to analyze and present the spatiotemporal patterns of precipitation across the state of Texas. To investigate precipitation patterns in Texas, this study gathered data from 42 weather stations across the state over a period of 70 years. The main objective is to analyze the spatial and temporal behavior of annual and seasonal precipitation in Texas by using the methodology proposed by Karl et al. (1999) and subsequently utilized in Rodrigo and Trigo's (2007) study of rainfall trends in the Iberian Peninsula. The methods used in this analysis may be applied to other locations of similar size where there are a reasonable number of individual weather stations with precipitation data available. The goal of this research can be broken down into a number of smaller objectives:

1) The first objective is to identify the temporal patterns of monthly, seasonal, and annual precipitation for the period of record. In order to accomplish this task, the data will be used to create three new variables; total precipitation, precipitation days, and precipitation intensity. A detailed statistical analysis will be performed on the three variables to determine whether precipitation is increasing, decreasing, or steady at each station.
2) This study will examine the spatial patterns of precipitation across the state for the period of record.
3) Another goal is to understand interannual variability expressed as dry and moist periods.

## Research Hypotheses

Several hypotheses were formulated to meet the objectives of this study and to address the following questions:

Group 1: Is total annual and seasonal precipitation increasing, decreasing, or staying steady at each station?

Group 2: Are annual and seasonal precipitation days (days with at least 0.1 mm precipitation) increasing, decreasing, or staying steady at each station?

Group 3: Is annual and seasonal precipitation intensity (precipitation per rain day) increasing, decreasing, or staying steady at each station?

The following hypotheses were grouped to the above questions:
Group 1: Total precipitation for each station:
A) $\mathrm{H}_{0}$ : No trend in annual total precipitation
$\mathrm{H}_{1}$ : A trend exists
B) $\mathrm{H}_{0}$ : No trend in winter precipitation
$\mathrm{H}_{1}$ : A trend exists
C) $\mathrm{H}_{0}$ : No trend in spring precipitation
$\mathrm{H}_{1}$ : A trend exists
D) $\mathrm{H}_{0}$ : No trend in summer precipitation
$\mathrm{H}_{1}$ : A trend exists
E) $\mathrm{H}_{0}$ : No trend in fall precipitation
$\mathrm{H}_{1}$ : A trend exists
Group 2: Precipitation days for each station:
A) $\mathrm{H}_{0}$ : No trend in annual total precipitation days
$\mathrm{H}_{1}$ : A trend exists
B) $\mathrm{H}_{0}$ : No trend in winter precipitation days
$\mathrm{H}_{1}$ : A trend exists
C) $\mathrm{H}_{0}$ : No trend in spring precipitation days
$\mathrm{H}_{1}$ : A trend exists
D) $\mathrm{H}_{0}$ : No trend in summer precipitation days
$\mathrm{H}_{1}$ : A trend exists
E) $\mathrm{H}_{0}$ : No trend in fall precipitation days
$\mathrm{H}_{1}$ : A trend exists
Group 3: Intensity for each station:
A) $\mathrm{H}_{0}$ : No trend in annual precipitation intensity
$\mathrm{H}_{1}$ : A trend exists
B) $\mathrm{H}_{0}$ : No trend in winter precipitation intensity
$\mathrm{H}_{1}$ : A trend exists
C) $\mathrm{H}_{0}$ : No trend in spring precipitation intensity
$\mathrm{H}_{1}$ : A trend exists
D) $\mathrm{H}_{0}$ : No trend in summer precipitation intensity
$\mathrm{H}_{1}$ : A trend exists
E) $\mathrm{H}_{0}$ : No trend in fall precipitation intensity
$\mathrm{H}_{1}$ : A trend exists

## Summary of Work

This dissertation is organized into separate chapters and is structured as follows: Chapter two consists of a detailed literature review outlining previous studies and approaches in precipitation research. Chapter three describes the study area, its physical attributes, and precipitation in Texas. Chapter four describes and illustrates the locations of the Texas weather stations, details the data acquisition and preparation, and methods used in the analysis. Chapter five presents the results, and chapter six includes an analysis and discussion of results. Chapter seven provides a conclusion, limitations, and suggestions for further research.

## CHAPTER 2

## LITERATURE REVIEW

Studies on precipitation cross a number of disciplines, and for this review, I have drawn upon the literature within the disciplines of climatology, geography, hydrology, and the atmospheric sciences. This chapter will consider precipitation measurement, and approaches to precipitation research in Texas, the United States, and internationally.

## Precipitation Measurement

The precipitation and climatological data resource books by Strangeways (2007) and Linacre (1992) discuss precipitation, its processes, its distribution in time and space, and measurement techniques. Early attempts at measuring precipitation were due to simple agricultural aids. For example, the need for regular rainfall for the cultivation of rice was an incentive for rain gauge measurement in Korea during the fifteenth century (Strangeways 2007). A bronze pillar instrument used as a rain gauge was introduced at the height of Korean civilization in 1441 and this instrument was used continuously until 1907 (Strangeways 2007).

In Europe, there were no known rain gauges until the seventeenth century (Strangeways 2007). A glass formed like a cylinder was a common rain gauge used during this particular period. The tipping bucket, a first known British gauge in the midseventeenth century resembles most of today's rain gauges. Since the eighteenth-century, a more developed academic approach arose out of scientific curiosity aided by improving
technology to measure precipitation (Strangeways 2007). Gilbert White, known for his Natural History of Selborne (1789), recorded a series of precipitation readings from May 1779 to December 1786. Yet, White's brother-in-law, who recorded and observed rainfall for 59 years in England, kept the longest record by one person, using the same rain gauge at that time (Strangeways 2007).

Over half a century later, George James Symons' interest in precipitation was inspired by drought conditions in the United Kingdom (UK). Symons collected precipitation data, experimented with various gauges in use at the time, and published his first volume of British Rainfall (Strangeways 2007). Symons devoted his time improving precipitation measurement and data collection. These improvements benefited the field of meteorology; however, this came at the cost of great financial difficulties for Symons (Strangeways 2007). Upon Symons' death in 1900, he was receiving precipitation records from 3500 sites and by the mid-nineteenth century, all basic rain gauge design principles had been established (Strangeways 2007).

## Measuring Precipitation with Rain Gauges

A rain gauge is a device that collects precipitation in the form of rain, drizzle, snow or hail, which is then measured. "The total precipitation is the sum of all liquid collected (including the water produced from melted solid precipitation), expressed as the depth it would cover on a flat surface assuming no losses due to evaporation, runoff, or percolation into the ground" (Strangeways 2007, 151). The common unit used in the past to measure precipitation was in inches. Although some countries still use this unit of measurement, millimeters are the more common unit used today for precipitation measurement.

The three most common types of rain gauges used to measure precipitation are the manual, mechanical, and electronic gauges. Although there are over 50 types of manual rain gauges used globally, the Symons 127 mm ( 5 in ) model has been the standard in the United Kingdom since the twentieth century (Strangeways 2007). The gauge has a cylindrical opening above a funnel, which takes the collected water into a vessel below and is measured on a daily basis with a graduated cylinder (Linacre 1992). The rim is placed one meter above the ground over short grass or gravel to prevent water splash from its surroundings. If the gauge is unable to be read on a daily basis, a larger container is used so that weekly or monthly amounts of precipitation can be collected and stored. The most widely used rain gauge in the United States is the $324 \mathrm{~cm}^{2}$ copper rain gauge (Strangeways 2007).

Mechanical chart recording gauges are used to provide information on the precise time when precipitation begins and ends at a station, and provides an approximate indication of precipitation rate (Strangeways 2007). The most common mechanical gauges used are the float-operated recorders and the weight-operated recording gauges. A typical float-operated recorder allows rain from the funnel to enter into a cylinder containing a float. As the water rises and enters, a pen records as it moves along a paper chart.

The tipping-bucket is the most common type of automatic electrical rain gauge in use today (Strangeways 2007). This rain gauge consists of two small buckets or levers that are balanced, and the bucket tips can be set to intervals of $0.1,0.2,0.25,0.5$, and 1 mm . As the precipitation falls onto one of the two small buckets and is equal to the
amount it is set to hold, the lever tips the bucket and an electrical signal is sent to the recording device (Strangeways 2007).

Measurement biases arise due to gauge under- catchment of precipitation, evaporative loss, out splash, leveling, the site of the gauge, human error, and wind which can significantly underestimate actual precipitation (Strangeways 2007). The most significant cause of error is typically turbulent airflow around the gauge that can deflect precipitation. A windshield can be placed around the gauge or the gauge can be placed into a pit with the rim at ground level to diminish the airflow problems.

## Measuring Precipitation using Radar and Satellite Technology

Radar and satellite technology do not replace the use of rain gauges to measure precipitation. Strangeways (2003) notes that the advantage that radar has over groundpositioned rain gauges is that it gives an areal estimate rather than a single location measurement. Radar technology observes the speed at which the rain falls, detects whether the rainfall is moving horizontally toward or away from the radar antenna, and gives the location and the intensity of the rainfall. Melting snow enhances the reflectivity and can create errors in overestimating rain intensity and drizzle is underestimated because it is hard to detect below the radar beam (Strangeways 2003). Satellites carry a variety of sensing instruments, which measure electromagnetic radiation (EMR) reflected from, or emitted by the atmosphere (Strangeways 2003). In addition, once the satellite has scanned the rain clouds and the EMR is collected, the data has to be inferred through a set of algorithms for interpretation.

Although precipitation data are subject to errors and biases, gauges that measure precipitation remain the most common approach to ground-based measurement (New et
al. 2001). Throughout the twentieth century, rain gauge measurements provide a wealth of information about trends and variability of precipitation (New et al. 2001). Satellite coverage for precipitation extends back only to 1974; however, the digital archives are growing and are continuing to provide coverage (New et al. 2001).

## Approaches to Precipitation Research

The precipitation characteristics most often studied include precipitation amount, precipitation intensity, and precipitation frequency (Brommer 2006). These characteristics provide valuable information concerning the general dryness or wetness of a location, and identify regional trends in precipitation (Palecki et al. 2005). The most common time scale for recording rainfall is daily accumulation (Palecki et al. 2005). Precipitation is often quantified through measurements at specific locations, and have typically been calculated over long averaging periods, such as monthly, seasonal, and annual time scales (Brommer 2006). These studies provide clues to important patterns in the variation of total precipitation, and the frequency and intensity of the rain events (Brommer 2006). The remainder of this chapter will review selected studies and research on precipitation patterns in other countries, the United States, and in Texas. These studies focus on research that uses rain gauge data. The studies address fundamental questions about precipitation characteristics, and determine the spatial and temporal patterns of precipitation over different time scales.

## Precipitation Studies in Other Countries

A large number of studies on precipitation trends exist and this section reviews selected studies of precipitation patterns internationally. The following studies utilized
rain gauge data to analyze precipitation patterns in the late nineteenth and twentieth centuries. Table 2.1 provides a summary for the studies discussed below.

Kiely et al. (1998) examined long-term trends in diurnal precipitation at Valentia on the west coast of Ireland from 1940 to 1993. The authors applied the Pettitt-MannWhitney statistical tests to hourly precipitation data and found a $10 \%$ increase in mean annual precipitation after 1975. The increase in precipitation was significant in March and October. Brunetti et al. (2001) examined changes in total precipitation, rain days, and extreme rain events in northeastern Italy for the period 1920-1998. Using a series of statistical tests (i.e. Craddock homogeneity and Mann-Kendall tests), the authors found a negative trend in the average annual number of wet days, and on a seasonal basis, a decrease in wet days is evident in spring and autumn.

Archer and Fowler (2004) examined the spatial and temporal variation in precipitation in the Upper Indus Basin of Pakistan from 1895 to 1999. Using correlation and regression, the authors did not find a significant trend in precipitation since 1895. However, there were significant increases occurred in winter, summer, and annual precipitation at several stations from 1961 to 1999. Moberg and Jones (2005) analyzed twentieth century trends in precipitation in Europe from 1901-1999. The authors conducted a linear trend analysis and results showed a seasonal increase in precipitation intensity and frequency during the winter months. Yu et al. (2006) evaluated long-term patterns in annual and seasonal precipitation from 1897-2001 in Taiwan using the cumulative deviation test, the Mann-Whitney-Pettitt, and Kruskal-Wallis statistical tests. The authors identified an annual increase in rainfall in northern Taiwan, and a decline in rainfall in the central and southern regions of the country.

Cheung et al. (2008) used a linear regression model to investigate temporal precipitation and its spatial distribution within Ethiopia. Using rain gauge data from 134 stations between 1960 and 2002, the authors did not find significant results in annual precipitation using the one-sample t-test. The authors did find a significant decline in precipitation from June to September in southwest and central Ethiopia. Other timeseries studies in Ethiopia reveal various results. Osman and Sauerborn (2002) found that summer precipitation in the central highland of Ethiopia declined during the latter half of the twentieth century, whereas Seleshi and Zasnke (2004) found a decline in annual precipitation in the eastern, southern, and southwestern regions of the country.

Using the Mann-Kendall and Sen's T statistical tests, Partal and Kahya (2006) analyzed trends in long-term annual mean and monthly total precipitation in Turkey from 1929 to 1993. They found a decrease in annual mean precipitation along the Black Sea coastline, and in the western and southern sections of the country. Rodrigo and Trigo (2007) analyzed trends in daily rainfall in the Iberian Peninsula from 1951 to 2002 using the Mann-Kendall statistic and linear regression model. Although the number of wet days did not reveal a significant change, the authors found that there was a decrease in daily intensity of rainfall on both annual and seasonal timescales.

## Precipitation Studies in the United States

This section reviews selected studies of precipitation patterns in the United States as summarized in Table 2.2. Lettenmaier et al. (1994) evaluated spatial patterns in precipitation for the period 1948-1988 in the contiguous United States. The authors applied the Kendall's test on the monthly and annual rainfall data and slope estimator to determine trend magnitudes. There was an increase in precipitation from September
through December at as many as 25 percent of the stations in the central part of the country (Lettenmaier et al. 1994).

Table 2.1. Summary of Recent Studies on Precipitation Trends Internationally

| Author(s) | Year | Location | Findings |
| :---: | :---: | :---: | :---: |
| Kiely et al. | 1998 | Valentia, Ireland | Ten percent increase in mean annual precipitation in March and October after 1975. |
| Brunetti et al. | 2001 | Northeastern Italy | Negative trend in the average annual number of wet days, and less wet days seasonally in the spring and autumn months. |
| Archer and Fowler | 2004 | Upper Indus Basin, Pakistan | No significant trend since 1895. However, significant increases in precipitation in winter, summer, and annually at several stations from 1961 to 1999 were noted. |
| Moberg and Jones | 2005 | Europe | Seasonal increases in precipitation intensity and frequency during the winter months. |
| Yu et al. | 2006 | Taiwan | Annual increase in rainfall in northern Taiwan. A decline in rainfall in the central and southern regions of the country were noted. |
| Partal and Kahya | 2006 | Turkey | A decrease in annual mean precipitation along the Black Sea coastline, and in the western and southern sections of the country. |
| Cheung et al. | 2008 | Ethiopia | No significant results in annual precipitation. A decline in precipitation from June to September in southwest and central Ethiopia was noted. |
| Osman and Sauerborn | 2002 | Ethiopia | A decline in summer precipitation during the latter half of the twentieth century. |
| Seleshi and Zasnke | 2004 | Ethiopia | A decline in annual precipitation in the eastern, southern, and southwestern regions. |
| Rodrigo and Trigo | 2007 | Iberian <br> Peninsula | No significant change in the number of wet days, however, there was a decrease in daily intensity of rainfall on both annual and seasonal time scales. |

Using daily data, Karl and Knight (1998) investigated monthly, seasonal, and annual precipitation patterns across the contiguous United States from 1919 to 1996. The authors found that precipitation increased (roughly 10\%) since 1910. They found that the proportion of annual precipitation derived from extreme events has increased relative to more moderate events, and that the number of events had increased significantly in every region across the contiguous United States (Karl and Knight 1998).

Kunkel and Andsager (1999) studied long-term twentieth century trends in extreme precipitation for the United States and Canada from 1931-1996. Using the Kendall tau statistic, the authors found lengthy periods of below-average number of precipitation events in the 1930s and 1950s, and an above-average number of precipitation events in the early 1940s, early 1980s, and 1990s. Kunkel et al. (2003) examined temporal variations in extreme precipitation in the United States from 1895 to 2000 and found similar results to the Kunkel and Andsager (1999) study. The authors found that the frequency of heavy precipitation events was greater in the late nineteenth and early twentieth centuries. Heavy precipitation decreased around the 1930s, followed by a general increase into the 1990s. Overall, the authors found that the frequency of extreme precipitation events was as high around the start of the twentieth century as it was toward the end of the twentieth century.

Stafford et al. (2000) examined precipitation trends in Alaska from 1949 to 1998. The total precipitation was analyzed for linear trends using least squares regression and analysis of variance (ANOVA) was used to determine seasonal and regional changes in precipitation. The authors found an increase in total precipitation for three of the four seasons, while summer precipitation decreased at many stations (Stafford et al. 2000).

Table 2.2. Summary of Recent Studies on Precipitation Trends in the United States

| Author(s) | Year | Location | Findings |
| :--- | :--- | :--- | :--- |
| Lettenmaier et al. | 1994 | Contiguous <br> United States | An increase in precipitation from <br> September through December was <br> noted at 25 percent of the stations in the <br> central part of the U.S. |
| Karl and Knight | 1998 | Contiguous <br> United States | Extreme events has changed <br> disproportionately and increased <br> relative to more moderate events. The <br> number of extreme events has increased <br> significantly in every region across the <br> contiguous United States. |
| Kunkel and | 1999 | United States <br> and Canada | Results show below average <br> precipitation events in the 1930s and <br> 1950s, and above average precipitation <br> events in the early 1940s, early 1980s, <br> and 1990s were noted. |
| Kunkel et al. | 2003 | United States | Frequency of heavy precipitation events <br> was greater in the late nineteenth and <br> early twentieth centuries. Heavy <br> precipitation decreased in the 1930s and <br> increased into the 1990s. |
| Stafford et al. | 2000 | Alaska | Increase in total precipitation for three <br> of the four seasons, while summer <br> precipitation decreased at many <br> stations. |
| Groisman et al. | 2004 | United States | Precipitation and very heavy <br> precipitation increased during the <br> twentieth century. |

Groisman et al. (2004) published a compilation of changes in the hydrologic cycle in the contiguous United States using daily precipitation data from 1961 to 1990. Using linear trend estimates, the authors found that precipitation and very heavy precipitation increased during the twentieth century (Groisman et al. 2004).

## Precipitation Studies in Texas

Few studies exist on the spatial and temporal precipitation patterns in Texas. A summary of recent studies is listed in Table 2.3. Lyons (1990) examined the spatial and temporal variability of monthly precipitation in Texas from 1923 to 1984 using synoptic analysis. Anomalously wet months in Texas correlated with a northward shift of high pressure, while dry months were associated with a southward shift in high pressure.

Harmel et al. (2003) examined long-term precipitation records from a rain gauge network located at the USDA-SC5 Blackland Experimental watershed facility near Riesel, Texas. The authors found increases in October rainfall, non-spring rainfall, and the number of rain days in both summer and fall.

Haragan (1978) examined the spatial and temporal variability of average precipitation of 63 stations in the Panhandle from 1944 to 1973. The author found a west-to-east precipitation gradient that increases near Miami in the month of May, whereas the same occurred over Palo Duro Canyon in June with a ridge extending southwestward to the town of Littlefield. In this analysis, the precipitation climatology showed that the local convection is influenced by topography in the Texas Panhandle.

Choi et al. (2008) examined a method to disaggregate daily rainfall into hourly precipitation in Texas. The method is based on measured precipitation data and generates disaggregated hourly hyetographs that match daily totals. This method can be applied and utilized to estimate precipitation intensity and duration.

Asquith (1998) examined depth-duration frequency (DDF) and intensity-duration frequency (IDF) of annual precipitation at the Tom Miller Dam on the Colorado River in Austin, Texas. Asquith (1998) computed DDF and IDF values and created a report with
tables listing the frequency data in minutes, hours, and days. The values are considered applicable and can be used by the City of Austin and Travis County in times of heavy precipitation events.

Table 2.3. Summary of Recent Studies on Precipitation Trends in Texas

| Author(s) | Year | Location | Findings |
| :--- | :--- | :--- | :--- |
| Lyons et al. | 1990 | Texas | Anomalously wet months correlated with a <br> northward shift of high pressure. Dry <br> months were associated with a southward <br> shift in high pressure. |
| Harmel et al. | 2003 | North Central <br> Texas | Increases in October rainfall, non-spring <br> rainfall, and the number of rain days during <br> the summer and fall months. |
| Choi et al. | 2008 | Texas | Examined a method to disaggregate daily <br> precipitation into hourly values. This <br> technique can be applied to estimate <br> precipitation intensity and duration. |
| Asquith | 1998 | Austin, Texas | Created a report with tables listing <br> precipitation frequency data in minutes, <br> hours, and days. This report can be used in <br> times of heavy precipitation events. |

## Summary

The research summarized in this chapter has addressed precipitation trends on global and local scales, and has revealed trends either spatially or temporally over many regions of the world. Although several studies show the spatial patterns of precipitation, many examined the temporal aspects that have resulted in an increase in precipitation towards the latter half of the twentieth century (Karl and Knight 1998; Kiely et al. 1998; Kunkel and Andsager 1999; Kunkel et al. 2003; Archer and Fowler 2004; and Groisman et al. 2004). When depicting changes in precipitation temporally, this may help answer
fundamental questions about precipitation characteristics that have not been addressed previously. For example, are these events lasting longer in duration? Is the duration of storm systems changing?

## CHAPTER 3

## THE STUDY AREA

## Location and Physical Geography of Texas

Texas is the largest state in the conterminous United States. It lies within latitudes $25^{\circ} 50^{\prime} \mathrm{N}$ to $36^{\circ} 30^{\prime} \mathrm{N}$ and longitudes $93^{\circ} 31^{\prime} \mathrm{W}$ to $106^{\circ} 39^{\prime} \mathrm{W}$. Texas is divided into 254 counties and covers an area of $678,051 \mathrm{~km}^{2}\left(261,797 \mathrm{mi}^{2}\right)$ (Figure 3.1). The state occupies approximately seven percent of the total U.S. water and land area with 950 $\mathrm{km}(367 \mathrm{mi})$ of coastline bordering the western Gulf of Mexico (Texas Almanac 2007). Along with the Gulf of Mexico, the Rio Grande River to the south and west, the Red River to the north, and Sabine River to the east all present natural borders.

Source: TAMIU, 2007.
Figure 3.1. The Study Area - Texas

The physiography of Texas spans a wide range of features from the High Plains to the north, the Guadalupe Mountains to the west, the Black Prairie to the east, and the coastal plains in the southeast and southern portions of the state. In Central Texas, the dominant landform is the Balcones Escarpment. This feature, originally formed along a fault zone, produced a sharp topographic break between the Great Plains and Gulf Coastal Plain physiographic boundaries (Petersen 1995) (Figure 3.2). Much of the state consists of flat plains, prairies, and plateaus.

Climatic variations exist from Texas' unique geographic location, movement of seasonal air masses, winds, and pressure systems (Figure 3.3). According to the Köppen climate classification system, Texas is a transition region between arid (BW), semi-arid (BS), and humid subtropical (Cfa) climates. The Gulf of Mexico moderates temperatures along the Gulf Coast, and both the Gulf of Mexico and the Pacific Ocean provide a major source of moisture for the region. The Rocky Mountains guide arctic cold fronts that move southward during the fall, winter, and early spring months. This allows the cold air masses to enter the state.

Mean annual temperatures across the state vary along latitudinal lines except for the mountainous regions in far west Texas. Based upon temperature data for the period 1961-1990, average temperatures range from $23.3^{\circ} \mathrm{C}\left(74^{\circ} \mathrm{F}\right)$ in the southern-most region of Texas near Brownsville, to $12.7^{\circ} \mathrm{C}\left(55^{\circ} \mathrm{F}\right)$ in the northern regions of the Panhandle (Bomar 1999). Average temperatures for the mountains in west Texas vary from $13.8{ }^{\circ} \mathrm{C}$ $\left(57^{\circ} \mathrm{F}\right)$ to $16.6^{\circ} \mathrm{C}\left(62^{\circ} \mathrm{F}\right)$ (Bomar 1999).

Figure 3.3. The interaction of seasonal air masses that affect the weather and climate in Texas.

## Precipitation in Texas

Based upon climatological data for the period 1961 to 1990, Texas is a transitional state between two radical precipitation regimes. Average annual precipitation in Texas decreases westward from $21.9 \mathrm{~cm}(8.63 \mathrm{in})$ at La Tuna near El Paso in the western region of the state, to 149.6 cm (58.93 in) near Orange, in the lower Sabine River valley in East Texas (Bomar, 1999) (Figure 3.4). In general, mean annual rainfall distribution in Texas follows longitudinal lines, and decreases approximately 25.4 mm (1 in) for each $24.1 \mathrm{~km}(15 \mathrm{mi})$ moving from east to west (Bomar 2001). The mountains in west Texas, and the Balcones Escarpment in central Texas, are characterized by an
increase in average annual precipitation, which presents the most obvious exception to the east-to-west increase in aridity (Swanson, 1995).

Figure 3.4. Average annual precipitation (in) for Texas, 1971-2000.
Figure 3.5 illustrates average precipitation (in) for each season based upon data from 1961-1990 (Bomar 1999). Over much of the state, spring is the wettest season of the year; however west Texas receives most of its rainfall during the summer months from convective storms. In the north central, central, and southeastern areas of the state, a secondary peak of rainfall at the end of summer or at the onset of autumn occurs due to tropical activity.

## CHAPTER 4

## METHODOLOGY AND DATA SOURCES

The National Oceanic and Atmospheric Administration's (NOAA) National Climatic Data Center (NCDC) developed the United States Historical Climatology Network (USHCN) to analyze U.S. climate and to assist in detecting regional climate change. The USHCN provides high quality data sets of meteorological variables from 1221 stations from the U.S. Cooperative Observing Network within the 48 contiguous United States (Easterling et al. 1996). The digital archive contains monthly and daily precipitation data for selected stations in the United States. The data for each of the stations in the USHCN are subjected to quality control, homogeneity testing, and adjustment procedures (Easterling et al. 1996). The selection of each station by the USHCN and the series of adjustments applied to the data make this database the best long-term precipitation data available for the contiguous United States. The original period of record varies for each station; however, the stations were selected for the USHCN based on length of period of record, percent missing data, number of station moves, and spatial coverage (Easterling et al. 1996). Metadata include the station history, information concerning station moves, instrumentation, observing times, and elevation.

## Data Preparation

This study used precipitation data from 42 stations in Texas covering the period of 1932 - 2002 (Figure 4.1). A list of the stations along with their station name, geographic coordinates, and elevation is given in Table 4.1. Due to similar climatic characteristics such as temperature, humidity, and precipitation, the stations were grouped into seven distinct regions: west, Panhandle, north central, northeast, central, southeast, and south (Table 4.2). For this study, the data set consists of monthly precipitation totals from the USHCN's database, and daily data from the National Climatic Data Center (NCDC). The daily data from the NCDC will be used to establish the number of days each station by month experienced at least 0.1 mm of precipitation. Daily data from the NCDC prior to 1954 is not available. For this study, the period of record for the daily data is 1955-2002. Although the most common units to use in an analysis of this caliber would be metric, this study will be using English units provided by the USHCN. A list of conversions is included in Appendix A.

## Missing Data

It is common practice to screen the data for missing values before the data can be used in the subsequent analysis. There are several reasons why precipitation may be missing from the database. Data may be missing due to rain gauge malfunction, floods, tornadoes, landslides, hurricanes, vandalism, and errors in reporting. Data estimation procedures were conducted to fill in the missing values. A common method to estimate missing precipitation data from a data set is regression analysis. For example, the data from one station (B) is compared with those from another station (A), and the hypothesis is made that simultaneous measurements at A and B have a constant relationship (Linacre 1992, 66). The missing precipitation values for each of the stations were estimated by using precipitation values from neighboring stations. The regression model allowed this
study to develop estimates and substitute missing monthly and precipitation day data for the 42 Texas stations. There was approximately less than 10 percent of the data missing between 1932 and 2002 for all stations total, and the regression models were used to estimate any missing values.

## Precipitation Variables

The monthly data from the USHCN was used to develop annual and seasonal totals for the 42 stations. Annual totals were tabulated from the monthly data for each station of each year during the period of record. Using the monthly precipitation data, seasonal totals for each year were created as follows: Winter (December of the previous year, January, February); Spring (March, April, May); Summer (June, July, August); and Fall (September, October, November).

The following three groups of variables were calculated for each station using the monthly data from the USHCN and daily data from the NCDC for the period of record.
(1) Total precipitation: The annual and seasonal amounts of precipitation. Period of record: 1932-2002.
(2) Precipitation Days: The number of days with a minimum precipitation of 0.1 mm for each season and year. Period of record: 1955 - 2002.
(3) Intensity Index: The intensity index (total precipitation divided by the number of days with precipitation) for each season and year. Period of record: 1955 2002.

The seasonal and annual calculations were performed from the monthly and daily data using Microsoft Excel. Once the annual and seasonal totals were calculated, the data for each station was transferred to SPSS for statistical analysis.

## Statistical Analysis and GIS Application

A variety of statistical techniques, both parametric and non-parametric were used to assess precipitation patterns in Texas. In applying these statistical tests, it was possible to examine linear trends, and whether or not areas around the state are becoming increasingly dry, wet, or that no changes exist.

## Descriptives

Basic descriptive statistics computed for this study included the mean, standard deviation, maximum, minimum, deciles, probability, and coefficient of variation.

Descriptive statistics were computed for each station for total precipitation, precipitation days, and precipitation intensity. Probability was computed using the precipitation day data and the mean values are illustrated in a series of maps.

## Linear Regression

Existence of a temporal trend was tested using linear regression on total precipitation, precipitation days, and precipitation intensity for all stations during the period of record. Using a linear regression model to analyze the statistical relationship between variables is common in climatological research. As an example, Rodrigo and Trigo (2007) utilized a linear regression model to show trends in daily rainfall in the Iberian Peninsula over a 51-year period. Karl and Knight (1998) utilized a linear regression model to illustrate trends in precipitation amount, frequency, and intensity for a period of 86 years during the twentieth century for the United States. In this analysis, linear regression was used to estimate the slope coefficient of the temporal trend in each
of the three precipitation variables. The slope of the line indicates direction and strength of the trend. Validation of the trend models consists of two parts: (1) a statistically significant slope coefficient, and (2) normally distributed residuals (using KolmogorovSmirnov statistical test). Tests were evaluated at the $95 \%$ level.

## Probability of Precipitation

For each station, the probability of a day with precipitation was calculated using daily data from 1955-2002. This value indicates the percentage of seasonally wet and dry days at each station. The probability of a day with precipitation was calculated as follows:

Probability of a day with precipitation $=\underline{100 \text { (number of days with precipitation) }}$ Number of days in season

## GIS

This study uses a geographic analysis mapping program (ArcMAP) for visualizing and spatially analyzing the linear regression results for total precipitation, precipitation days, and precipitation intensity for all 42 stations. The spatial distribution of the trends was depicted by using graduated symbol maps. Annual and seasonal mean values for the coefficient of variability and probability of a day with precipitation was mapped for all 42 stations.

## CHAPTER 5

## RESULTS

The diversity in climate conditions for the state of Texas varies from the arid conditions in the west to wetter conditions in the eastern section of the state. The variety of weather elements that characterize the climate of Texas is not due to its size, but to its position on the North American continent. Texas weather is unique and is due to its proximity to the warm Gulf of Mexico waters, the wind flow from the eastern North Pacific, and the cooler air from the north. This keeps Texas weather in a constant state of change. Precipitation decreases from east to west with half of the state, mainly the western half, receiving less than 30 inches of precipitation on average per year (Bomar 1999). For this study, Texas is divided into seven regions with similar climatic characteristics such as temperature, humidity, and precipitation (Figure 5.1). The seven regions include west, Panhandle, north central, northeast, central, southeast, and south.

This chapter presents a description of the climate for each region and station in Texas, and the results of the statistical analyses for the 42 study stations. The climate for the individual stations was determined using the Koppen climate classification system. Annual precipitation and annual temperature data from the USHCN from 1971-2000 were used to determine the climate for the individual stations. The stations used in this study were classified as either as B (arid or semi-arid) climate, or a C (humid subtropical) climate type. Descriptive statistics are presented for annual and seasonal total precipitation, precipitation days, and precipitation intensity. For each station, the mean,
standard deviation, maximum and minimum, deciles, the coefficient of variation (CV), and probability is given in a series of tables. Second, linear regression was used to determine the magnitude of the linear temporal trend in annual and seasonal total precipitation, precipitation days, and precipitation intensity. Statistical significance was at the 0.05 level. For each region, a discussion of the results for annual and seasonal precipitation is presented.

## West Texas

West Texas is mountainous and borders New Mexico to the west and Mexico to the south. In this region there are three distinct Köppen climate types; BWk (mid-latitude cold desert), BSh (semi-arid hot steppe), BSk (semi arid cold steppe), and BWh (arid hot desert). The six weather stations in this region are El Paso (17), Balmorhea (4), Alpine (3), Pecos (35), Ft. Stockton (21), and McCamey (30) (Figure 5.1).

Figure 5.1. Texas Weather Stations and Regions

## El Paso

El Paso is located on the far western edge of Texas and is classified as a middle latitude desert climate (Köppen climate classification BWh) with hot summers, low humidity, and mild to cool, dry winters. Descriptive statistics for total precipitation, precipitation days, precipitation intensity, and probability are given in Tables 5.1, 5.2, 5.3, and 5.4. Annual total precipitation averages 8.33 inches, of which the largest portion occurs during the summer months. Annually, this station receives an average of 22.25 days of precipitation. Precipitation intensity averages 0.3901 inch per day. Seasonally, the minimum amount of precipitation occurred during the winter months, whereas the maximum amount of precipitation occurred during the summer months. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while spring is the most variable. For precipitation days, the CV suggests that the summer months have the least variability, while the spring is the most variable. The winter months show the smallest amount of variability in precipitation intensity, while fall is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity is less than their respective mean values, except for summer and spring precipitation intensity. The decile values are given in each of the descriptive statistic tables below and provide an indication of the spread of observations for the period of record. The results show that in $10 \%$ of the years on record, annual precipitation will be at or below 5.36 inches. Ninety percent of the years will be at or below 12.53 inches, with $10 \%$ being above 12.53 inches. For precipitation days, results show that in $10 \%$ of the years on record, annual number of days will be at or below 14 days. Ninety percent will be at or below 32.1 days, with $10 \%$ being above 32.1 days.

For precipitation intensity, results show that $10 \%$ of the years on record was at or below 0.30 inch per day. Ninety percent of the years had 0.48 inch per day or less. Probability results show that this station has a $6.09 \%$ chance that any one day in the year would receive 0.1 mm of rain. No significant trend in the precipitation variables was discerned (Table 5.5).

## Balmorhea

Balmorhea is classified as a middle latitude desert climate (Köppen climate
classification BSk) semi-arid with hot summers, and mild to cool winters. Descriptive
statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.6, 5.7, 5.8, and 5.9. Annual total precipitation averages 13.03 inches of which the largest portion occurs during the fall and summer months. Annually, this station receives an average of 27.71 days of precipitation per year, most of which occurs during the summer months. Precipitation intensity averages 0.47 inch per day on an annual basis with the fall months receiving the highest precipitation intensity. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while fall is the most variable. For precipitation days, the CV suggests that the summer months have the least variability, while the winter is the most variable. The summer months show the smallest amount of variability in precipitation intensity, while fall is the most variable. The data show that over the period of record, $50 \%$ of the total precipitation, precipitation days, and precipitation intensity is below their respective mean values. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 6.59 inches. Ninety percent will be at or below 20.90 inches, with $10 \%$ above 20.90 inches. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 19 days. Ninety percent will be at or below 41 days, with $10 \%$ being above 41 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.33 inch per day. Ninety percent of the years had 0.65 inch per day or less. Probability results show that this station has a $7.59 \%$ chance of an increase in annual precipitation days per century. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values. Probability results show that this
station has a $7.59 \%$ chance that any one day in the year would receive 0.1 mm of rain. No significant trend in the precipitation variables was discerned (Table 5.10).

## Alpine

Alpine is the southern most station in the west Texas division. This station is classified as a middle latitude desert climate (Köppen climate classification BSk) semiarid with hot summers, and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.11, 5.12, 5.13, and 5.14. Annual total precipitation averages 15.99 inches, of which the largest portion occurs during the summer months. Annually, this station receives an average of 32.08 days of precipitation, most of which occurs during the summer months. Precipitation intensity averages 0.50 inch per day on an annual basis, with the summer and fall months receiving the highest precipitation intensity. A comparison of the CVs suggests that the summer season has the smallest amount of precipitation variability, while the winter is most variable. For precipitation days, the CV suggests that the summer season has the smallest amount of variability, while the winter is most variable.

For precipitation intensity, fall months have the smallest amount variability, while the spring is most variable. The data show that over the period of record, $50 \%$ of the total precipitation, precipitation days, and precipitation intensity is below their respective mean values. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 9.25 inches. Ninety percent will be at or below 22.89 inches, with $10 \%$ above 22.89 inches. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 22.90 days. Ninety percent will be at or below 41 days, with $10 \%$ being above 41 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.36 inch per day. Ninety percent of the years had 0.71 inch per day or less. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values. Probability results show that this station has an $8.78 \%$ chance that any one day in the year would receive 0.1 mm of rain. No significant trend in the precipitation variables was discerned (Table 5.15).

## Pecos

The climate of Pecos is classified as a middle latitude desert climate (Köppen climate classification BWh) with hot summers, low humidity, and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.16, 5.17, 5.18, and 5.19. Annual total precipitation averages 10.37 inches, of which the largest portion occurs during the summer and fall months. Annually, this station receives an average of 23.44 days of precipitation, most of which occurs during the fall and summer months. Precipitation intensity averages 0.48 inch per day on an annual basis, with the summer and fall months receiving the highest precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual and summer precipitation days. A comparison of the CV suggests that the summer season has the smallest amount of precipitation variability, while spring is the most variable. For precipitation days, the CV suggests that the summer season has the smallest amount of variability, while the fall is the most variable. The summer months have the smallest variability with regards to precipitation intensity, while the winter is most variable. The median values of total precipitation, precipitation days, and precipitation intensity is less than their respective mean values except for annual and summer season precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 5.14 inches. Ninety percent had 17.46 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 15 days. Ninety percent will be at or below 31 days, with $10 \%$ being above 31 days. For precipitation intensity, results show that $10 \%$ of the years
on record experienced at or below 0.23 inch per day. Ninety percent of the years had 0.80 inch per day or less. Probability results show that this station has a $6.42 \%$ chance that any one day in the year would receive 0.1 mm of rain. No significant trend in the precipitation variables was discerned (Table 5.20).

## Ft. Stockton

The climate of Ft. Stockton is classified as a middle latitude desert climate (Köppen climate classification BSh) semi-arid with hot summers, and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables $5.21,5.22,5.23$, and 5.24. Annual total precipitation averages 13.27 inches, of which the largest portion occurs during the summer and fall months. Annually, this station receives an average of 27.17 days of precipitation, most of which occurs during the summer and fall months. Precipitation intensity averages 0.49 inch per day on an annual basis with the summer and fall months receiving the highest precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual precipitation and summer precipitation intensity. A comparison of the CV suggests that the summer season has the smallest amount of precipitation variability, while the winter
is most variable. For precipitation days and precipitation intensity, the CV suggests that the summer months have the smallest amount of variability, while the winter months are most variable. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 7.84 inches. Ninety percent will be at or below 19.80 inches, with $10 \%$ above 22.89 inches. For precipitation days, results show that $10 \%$ of the years on record, annual number of days will be at or below 15 days. Ninety percent will be at or below 37.20 days, with $10 \%$ being above 37.20 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.38 inch per day. Ninety percent of the years had 0.63 inch per day or less. Probability results show that this station has a $7.44 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results reveal a significant finding in annual intensity with 0.002 inch increase per precipitation day. Twelve percent of the variance is accounted for by the regression (Table 5.25).

## McCamey

The climate of McCamey is classified as a hot, semi-arid steppe (Köppen climate classification BSh) with hot summers, low humidity, and mild to cold, dry winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.26, 5.27, 5.28, and 5.29. Annual precipitation averages 13.69 inches, most of which occurs during the summer and fall months. Annually, this station receives an average of 25.52 days of precipitation, of which the largest portion occurs during the summer and fall months. Annually, precipitation intensity averages 0.53 inch per day with the summer and fall months receiving the highest precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values. A comparison of the CV suggests that the summer season has the smallest amount of variability, while the fall is the most variable. For precipitation days, the CV suggests that the summer months have the smallest amount of variability, while the winter is the most variable. Spring precipitation intensity has the smallest amount of variability while the fall months are the most variable. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 7.71 inches. Ninety percent will be at or below 19.51 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 18 days. Ninety percent will be at or below 35 days, with $10 \%$ being above 35 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.42 inch per day. Ninety percent of the years had 0.69 inch per day or less. Probability results show that this station has a $6.99 \%$
chance that any one day in the year would receive 0.1 mm of rain. Linear regression results reveal a significant finding in the number of precipitation days. Results show an increase of .078 days per year in the summer months during the period of record with $13.3 \%$ of the variance accounted for by the regression. (Table 5.30).

## Summary for West Texas

Most precipitation falls during the summer months for all west Texas stations.
All stations showed more precipitation days during the summer months, while a majority of stations had higher precipitation intensity values during the fall months. The summer months showed the least amount of variability for precipitation and precipitation days for all stations, while the cooler months of spring, fall, and winter yielded higher variability during the period of record. All seasons, except summer, resulted in higher variability for precipitation intensity, with the fall months having the majority among the stations. The highest probability of a rain day for the stations was $8.78 \%$ for Alpine. All other stations fell below this value. Most stations resulted in a positive skew for precipitation, precipitation days, and precipitation intensity. Median values fell less than the mean
except for spring and summer intensity for El Paso, annual and summer precipitation days for Pecos, and summer precipitation intensity for Ft. Stockton.

Total precipitation, precipitation days, and precipitation intensity annually and seasonally were grouped into equal frequency deciles. For the given stations, the bottom deciles included the $10 \%$ of events with the lowest values, while the top decile include the $10 \%$ of events with the greatest value. Pecos resulted in the lowest value for annual precipitation with $10 \%$ of the years not exceeding 5.14 inches of precipitation. For Alpine, $10 \%$ of the years on record exceeded 22.89 inches of precipitation. El Paso resulted in the lowest value for precipitation days and intensity, with $10 \%$ of the years not exceeding 14 days and 0.030 inch per day of precipitation. For Ft. Stockton, $10 \%$ of the years on record exceeded 37 days of precipitation, while Pecos exceeded 0.80 inch per day. There is a statistically significant increase in annual precipitation intensity of 0.002 inch per day over the period of record for Ft. Stockton, while a statistically significant increase of 0.078 in precipitation days during the summer months was found for McCamey. No other trends were found.

## The Panhandle

The Panhandle is the most northerly region in Texas, bordered by the state of New Mexico to the west and Oklahoma to the north and east. Summers are hot and the winter months are cold with moderate snowfall. Precipitation from storms is most frequent during the spring and early summer months. These storms are a result of the movement of the "Marfa Front" or "dry line"; a sharp gradient in low-level moisture not present in the late summer months (Bomar 1999). In this region, the BSk (mid-latitude cold steppe) is the only climate type common to the stations of the region. The six
weather stations and their respective station number in this region include Seminole (39), Snyder (40), Crosbyton (13), Muleshoe (33), Plainview (36), and Miami (32) (Figure 5.1).

## Seminole

Seminole (Köppen climate classification BSk) is the southern most station in the Panhandle region. This climate is classified as semi-arid with hot summers, and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.31, 5.32, 5.33, and 5.34. Annual precipitation averages 16.60 inches, of which the largest portion occurs during the summer months. Annually, this station receives an average of 32.58 days of precipitation, most of which occurs during the summer months. Annually, precipitation intensity averages 0.52 inch per day. The winter months receive the least amount of precipitation per day while the summer receives more. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except annual precipitation, spring and summer precipitation days, and annual and summer precipitation intensity. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the summer months for precipitation days have the smallest amount of variability, while the winter months are most variable, and the spring months have the smallest variability for precipitation intensity while the summer months are most variable. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 8.16 inches. Ninety percent will be at or below 24.17 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of
the years on record, annual number of days will be at or below 23.9 days. Ninety percent will be at or below 43 days, with $10 \%$ being above 43 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.39 inch per day. Ninety percent of the years had 0.66 inch per day or less. Probability results show that this station has an $8.93 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not indicate significant findings in regard to an increase or decrease in precipitation, precipitation days, or precipitation intensity during the period of record (Table 5.35).

## Snyder

Snyder is classified as a semi-arid cold steppe (Köppen climate classification BSk) with hot summers and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.36, 5.37, 5.38, and 5.39. Annual precipitation averages 20.90 inches, of which the largest portion occurs during the summer months. Annually, this station receives an average of 36.25 days of precipitation, most of which occurs during the summer months. Annually, precipitation intensity averages 0.59 inches per day. The winter months receive the least amount of precipitation per day, while the summer receives the most. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for fall and summer precipitation days. A comparison of the CV suggests that the spring months has the smallest amount of precipitation variability, while the winter is most variable. For precipitation days, the CV suggests that the summer months have the smallest amount of variability, while the winter is most variable. All seasons are fairly uniform in variability with regards to precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 12.58 inches. Ninety percent will be at or below 29.89 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 26.80 days. Ninety percent will be at or below 45.10 days, with $10 \%$ being above 45.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.46 inch per day. Ninety percent of the years had 0.78 inch per day or less. Probability results show that
this station has a $9.93 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show a significant finding in winter precipitation intensity with an increase of 0.004 inch per precipitation day, and $23.3 \%$ of the variance is accounted for by the regression.

## Crosbyton

Crosbyton is classified as a semi-arid desert (Köppen climate classification BSk) with hot summers and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.41, 5.42, 5.43, and 5.44. Annual precipitation averages 21.86 inches, of which the largest portion occurs during the summer months. Annually, this station receives an average of 40.08 days of precipitation, most of which occurs during the summer months. Annually, this station averages 0.5439 inch per day with most occurring during the fall months. The winter months receive the least amount of precipitation per day. A comparison of the CV suggests that the summer months has the smallest amount of precipitation variability, while the winter is most variable. For precipitation days, the CV suggests that the spring, summer, and fall months are fairly uniform and have the smallest amount of precipitation
variability, while the winter months is most variable. The summer months resulted in the smallest amount variability in regards to precipitation intensity, while the fall is most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values except for annual precipitation days and fall precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 14.62 inches. Ninety percent will be at or below 29.39 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 29.90 days. Ninety percent will be at or below 50 days, with a $10 \%$ being above 50 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.45 inch per day. Ninety percent of the years had 0.63 inch per day or less. Probability results show that this station has a $10.98 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not indicate significant findings in regard to an increase or decrease in precipitation, precipitation days, or precipitation intensity during the period of record (Table 5.45).

## Muleshoe

Muleshoe is classified as semi-arid cool steppe (Köppen climate classification BSk) with hot summers, and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.46, 5.47, 5.48, and 5.49. Muleshoe receives an average of 17.18 inches precipitation per year, with most occurring during the summer months. Annually, this station receives an average of 35.38 days of precipitation, of which the largest portion occurs during the summer months. Annually, this station averages 0.48 inch of precipitation per day with most occurring during the summer and fall months. The winter months receive the least amount of precipitation per day. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while the spring is the most variable. For precipitation days, the CV suggests that the summer months have the
smallest amount of variability, while the winter is most variable. The spring months show the smallest amount of variability in regards to precipitation intensity, while the fall months are most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values except for spring precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 11.81 inches. Ninety percent will be at or below 21.85 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 28 days. Ninety percent will be at or below 44.10 days, with a $10 \%$ being above 44.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.39 inch per day. Ninety percent of the years had 0.59 inch per day or less. Probability results show that this station has a $9.69 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not indicate significant findings in regard to an increase or decrease in precipitation, precipitation days, or precipitation intensity during the period of record (Table 5.50).

## Plainview

Plainview is classified as a semi-arid cool steppe (Köppen climate classification BSk) with hot summers, and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.51, 5.52, 5.53, and 5.54. Plainview receives an average of 19.04 inches of precipitation per year, with most occurring during the summer months. Annually, this station receives an average of 36.81 days of precipitation, of which the largest portion occurs during the summer months. Annually, this station averages 0.54 inch of precipitation per day, with most occurring during the summer months. The winter months receive the least amount of precipitation per day. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while the winter is most variable. For precipitation days, the CV suggests that the summer months have the smallest amount of variability, while the winter is most variable. The CV suggests that the winter months
have the smallest amount of variability for precipitation intensity, while the spring is most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 13.36 inches. Ninety percent will be at or below 26.65 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 29.80 days. Ninety percent will be at or below 47 days, with $10 \%$ being above 47.00 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.44 inch per day. Ninety percent of the years had 0.69 inch per day or less. Probability results show that this station has a $10.08 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not indicate significant findings in regard to an increase or decrease in precipitation, precipitation days, or precipitation intensity during the period of record (Table 5.55).

## Miami

Miami is classified as a semi-arid cool steppe (Köppen climate classification BSk) with hot summers, and mild to cool winters. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.56, 5.57, 5.58, and 5.59. Miami receives an average of 22.02 inches of precipitation per year, of which the largest portion occurs during the summer months. Annually, this station receives an average of 40.90 days of precipitation, most of which occurs during the summer months. Annually, this station averages 0.5567 inch per day, most of which is relatively uniform between the spring, summer, and fall months. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while the winter is the most variable. For precipitation days, the CV suggests that the summer months have the smallest amount of variability, while the winter is the most variable, and the summer months show the smallest amount of variability in regards to precipitation intensity, while the winter is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual and summer precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 14.80 inches. Ninety percent will be at or below 29.31 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 32.80 days. Ninety percent will be at or below 50.10 days, with $10 \%$ being above 50.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.40 inch per day. Ninety percent of the years had 0.71 inch per day or less. Probability results show that this station has an $11.20 \%$ chance that any one day in the
year would receive 0.1 mm of rain. Linear regression results show significant findings in annual total precipitation with an increase in 0.073 inch of precipitation per year with $6.4 \%$ of the variance accounted for by the regression, and an increase in winter precipitation intensity with 0.0067 inch increase per precipitation day with $16.2 \%$ of the variance accounted for by the regression (Table 5.60).

## Summary for the Panhandle

Most precipitation falls during the summer months for all Panhandle stations. All stations showed more precipitation days during the summer months, while a majority of stations resulted in higher precipitation intensity during the summer months, except Crosbyton during fall months. The summer months resulted in the least amount of variability for precipitation and precipitation days for all stations, while the winter yielded more variability. All seasons resulted in higher variability for precipitation intensity, with the fall months being the majority among the stations. The highest probability of a rain day was $11.20 \%$ for Miami. All other stations fell below this value. Most stations resulted in a positive skew for precipitation, precipitation days, and precipitation intensity. Median values fell less than the mean except for annual precipitation, spring, and summer precipitation days, and annual, summer, and spring precipitation intensity for Seminole; fall and summer precipitation days for Snyder; annual precipitation days and fall precipitation intensity for Crosbyton; spring precipitation days for Muleshoe; and annual summer precipitation days for Miami.

Total precipitation, precipitation days, and precipitation intensity annually and seasonally were grouped into equal frequency deciles. For the given stations, the bottom decile included the $10 \%$ of events with the lowest values, while the top decile include the ten percent of events with the greatest value. Seminole resulted in the lowest values for precipitation with $10 \%$ of the years not exceeding 8.16 inches of precipitation 23.9 precipitation days, and 0.39 inch per day. For Snyder, $10 \%$ of the years on record exceeded 29.89 inches of precipitation and 0.78 inch per day. For Miami, $10 \%$ of the years on record exceeded 50.10 days of precipitation. There is a statistically significant
increase in winter precipitation intensity of 0.004 inch per precipitation day over the period of record for Snyder, and a 0.0067 inch per precipitation day during the winter for Miami during the period of record. No other trends were found.

## North Central

The North Central region is classified as subtropical with hot, humid summers. In this region, there is one distinct climate type based on the Köppen climate classification; Cfa (humid subtropical). This division has a bimodal precipitation pattern with May and September being the wettest months (Swanson 1995). Precipitation in May is a result of frontal storms from the north, and September precipitation is a result of frontal systems from the north, and tropical systems that migrate out of the Gulf of Mexico in the early fall months (Swanson 1995). The five weather stations in this region include Haskell (24), Albany (1), Brownwood (9), Dublin (15), and Weatherford (42) (Figure 5.1).

## Haskell

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.61, 5.62, 5.63, and 5.64. Haskell (Köppen climate classification Cfa) receives an average of 24.55 inches of precipitation per year, with most occurring during the summer months. Annually, this station receives an average of 41.06 days of precipitation, of which the largest portion occurs during the spring months. Annually, this station averages 0.6119 inch per day with most occurring during the summer months. A comparison of the CV suggests that the spring months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV shows that the summer months have the smallest amount of
variability, and the winter is the most variable. The spring months show the least variability in precipitation intensity, while the summer is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 15.87 inches. Ninety percent will be at or below 33.15 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 31.80 days. Ninety percent will be at or below 51.10 days, with $10 \%$ being above 51.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.48 inch per day. Ninety percent of the years had 0.72 inch per day or less. Probability results show that this station has an $11.25 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant trends in fall and winter precipitation intensity. Results show a decrease of 0.005 inch per precipitation day in fall intensity, with $12.7 \%$ of the variance accounted for by the regression. In addition, there is a 0.004 inch per precipitation day increase in winter precipitation intensity with $12.3 \%$ of the variance was accounted for by the regression (Table 5.65).

#### Abstract

Albany

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.66, 5.67, 5.68, and 5.69. Albany (Köppen climate classification Cfa) receives an average of 27.51 inches of precipitation per year, of which the largest portion occurs during the spring months. Annually, this station receives an average of 42.63 days of precipitation, most of which occurs during the spring months. Annually, this station averages 0.6639 inch per day with most occurring during the summer months. A comparison of the CV suggests that the spring months have smallest amount of precipitation variability, while the winter is the most variable. For precipitation days, the CV suggests that the summer months have the least variability, while the winter is the most variable. The spring months show the smallest amount of variability in precipitation intensity, while the summer is the most variable. The median

values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual and summer precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 17.18 inches. Ninety percent will be at or below 38.22 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 32.90 days. Ninety percent will be at or below 53.10 days, with $10 \%$ being above 53.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.48 inch per day. Ninety percent of the years had 0.86 inch per day or less. Probability results show that this station has an $11.67 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not indicate significant findings in regard to an increase or decrease in precipitation, precipitation days, or precipitation intensity during the period of record (Table 5.70).

## Brownwood

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.71, 5.72, 5.73, and 5.74. Brownwood (Köppen climate classification Cfa) receives an average of 28.27 inches of precipitation per year, with most occurring during the spring, summer, and fall months. Annually, this station receives an average of 41.92 days of precipitation, of which the largest portion occurs during the spring months. Annually, this station averages 0.68 inch per day, with most occurring during the fall months. A comparison of the CV suggests that the spring months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the summer months have the least variability, while the winter is the most variable. The spring months show the smallest amount of variability in precipitation intensity, while summer is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual and fall precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 19.98 inches. Ninety percent will be at or below 37.02 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 30 days. Ninety percent will be at or below 52.10 days, with $10 \%$ being above 52.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.53 inch per day. Ninety percent of the years had 0.85 inch per day or less. Probability results show that this station has an $11.48 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual, spring, and summer
precipitation intensity. Results show annual precipitation intensity increasing at 0.002 inch of precipitation per precipitation day, with $8.9 \%$ of the variance accounted for by the regression, and spring months with an increase of 0.004 inch of precipitation per precipitation day, with $10.5 \%$ of the variance accounted for by the regression. Summer months show an increase of 0.005 inch of precipitation per precipitation day with $8.6 \%$ of the variance accounted for by the regression (Table 5.75).

## Dublin

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables 5.76, 5.77, 5.78, and 5.79. Dublin (Köppen climate classification Cfa ) receives an average of 33.80 inches of precipitation per year, with most occurring during the spring, summer, and fall months. Annually, this station receives an average of 51.58 days of precipitation, of which the largest portion occurs during the spring months. Annually, this station averages 0.67 inches per day, with most occurring during the fall months. A comparison of the CV suggests that the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the spring months have the smallest amount of variability while the winter is most variable for precipitation days and precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for spring precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 23.57 inches. Ninety percent will be at or below 44.40 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 41.80 days. Ninety percent will be at or below 64.20 days, with $10 \%$ being above 64.20 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.53 inch per day. Ninety percent of the years had 0.88 inch per day or less. Probability results show that this station has a $14.13 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and summer total precipitation and annual, summer and winter precipitation intensity. Results show an increase of 0.105 inch per
year in annual total precipitation with $7.0 \%$ of the variance accounted for by the regression, and an increase of 0.066 inch per year during the summer months with $11.2 \%$ of the variance accounted for by the regression. In addition, results show an increase of 0.003 inch per precipitation day annually with $14 \%$ of the variance accounted for by the regression, and an increase of 0.005 precipitation per precipitation day during both the summer and winter months with $10.3 \%$ and $16.7 \%$ of the variance accounted for by the regression, respectively. Fall and spring shows an increase of 0.001 inch per precipitation day with approximately $1 \%$ of the variance accounted for by the regression (Table 5.80).

## Weatherford

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity are given in Tables $5.81,5.82,5.83$, and 5.84. Weatherford (Köppen climate classification Cfa ) receives an average of 33.37 inches of precipitation per year, with most occurring during the spring months. Annually, this station receives an average of 50.35 days of precipitation, of which the largest portion occurs during the spring months. Annually, this station averages 0.67 inch per day with most occurring during the fall months. A comparison of the CV shows that the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV shows that the spring months have the smallest amount of variability, while the winter months are most variable for precipitation days. The spring months show the smallest amount of variability, while the winter is most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 22.69 inches. Ninety percent will be at or below 44.04 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 37.90 days. Ninety percent will be at or below 60.10 days, with $10 \%$ being above 60.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.52 inch per day. Ninety percent of the years had 0.83 inch or less. Probability results show that this station has a $13.79 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not
show significant findings in total precipitation, precipitation days, or precipitation intensity (Table 5.85).

Summary for the North Central Region

Most precipitation and days with precipitation occur during the spring months for all North Central stations. Precipitation intensity is greatest during the fall months except for Haskell and Albany. The summer and spring months showed the least amount of variability for precipitation and precipitation days, while the variability for precipitation intensity was low during the spring months. The highest probability of a rain day resulted in $14.13 \%$ for Dublin. All other stations fell below this value. Most stations show a positive skew for precipitation, precipitation days, and precipitation intensity. Median values fell less than the mean except for annual and summer precipitation days for Albany; annual and fall precipitation days for Brownwood; spring precipitation days for Dublin; and annual precipitation intensity for Weatherford.

Total precipitation, precipitation days, and precipitation intensity annually and seasonally were grouped into equal frequency deciles. For the given stations, the bottom deciles included the $10 \%$ of events with the lowest values, while the top deciles include the $10 \%$ of events with the greatest value. Haskell showed the lowest values for precipitation with $10 \%$ of the years not exceeding 15.87 inches of precipitation, and 0.48 inch per day. Albany showed the lowest values for precipitation intensity with $10 \%$ of the years not exceeding 0.48 inch per day, and Brownwood with 30.00 precipitation days. For Dublin, $10 \%$ of the years exceeded 44.40 inches of precipitation, 64.20 precipitation days, and 0.88 inch per day.

There is a statistically significant increase of 0.105 inch of precipitation per year over the period of record for annual precipitation and 0.066 inch per year during the summer months for precipitation during the period of record for Dublin. Stations that experienced an increase in annual precipitation intensity include Brownwood and Dublin, and those stations that experienced an increase in winter precipitation include Haskell and Dublin. Haskell is the only station that resulted in a decrease in precipitation intensity during the fall months, while Brownwood and Dublin resulted in an increase in precipitation intensity during the summer months. Brownwood also resulted in an increase in spring precipitation intensity. No other trends were found.

## Northeast

The Northeast region is classified as subtropical with hot, humid summers. In this region, there is one distinct climate type based on the Köppen climate classification; Cfa (humid subtropical). This region receives humid air from the Gulf of Mexico from the south during the summer months, and cyclonic storms from the north during the winter
months. The five weather stations and their respective station number in this region include Mexia (31), Corsicana (12), Greenville (22), Clarksville (10), and Marshall (29) (Figure 4.1).

## Mexia

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Mexia are given in Tables 5.86, 5.87, 5.88, and 5.89. Mexia (Köppen climate classification Cfa) receives an average of 39.31 inches of precipitation per year with most occurring during the spring months. Annually, this station receives an average of 55.83 days of precipitation, of which the largest portion occurs during the spring months. Annually, this station averages 0.72 inch per day with most occurring during the fall months. A comparison of the CV suggests that the spring months have smallest amount of precipitation variability, while the fall is most variable. The CV shows that the spring months have the smallest amount of variability, while the fall is most variable for precipitation days. The CV shows that the spring months have the smallest amount a variability, while the fall months is most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for fall total precipitation, and winter and fall precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 26.92 inches. Ninety percent will be at or below 52.94 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 41.70 days. Ninety percent will be at or below 69 days, with $10 \%$ being above 69.00 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.59 inch
per day. Ninety percent of the years had 0.85 inch per day or less. Probability results show that this station has a $15.29 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and winter precipitation intensity. Results show an increase of 0.002 inch of precipitation per precipitation day annually, with $9.3 \%$ of the variance accounted for by the regression, and an increase of 0.006 inch precipitation per precipitation day during the winter months, with $10.9 \%$ of the variance accounted for by the regression (Table 5.90).

## Corsicana

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Corsicana are given in Tables 5.91, 5.92, 5.93, and 5.94. Corsicana (Köppen climate classification Cfa) receives an average of 38.20 inches of precipitation per year, of which the largest portion occurs during the spring months. Annually, this station receives an average of 55.08 days of precipitation, most of which occurs during the spring months. Annually, this station averages 0.69 inch per day with most occurring during the fall months. A comparison of the CV suggests the winter and spring months have the smallest amount of precipitation variability, while the summer is most variable. The CV suggests that the spring months have the smallest amount of variability, while the summer is the most variable for precipitation days. The CV suggests that the summer months have the smallest amount of variability, while the spring months are most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for spring precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 27.99 inches. Ninety percent will be at or below 49.15 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 42.90 days. Ninety percent will be at or below 67.10 days, with $10 \%$ being above 67.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.56 inch per day. Ninety percent of the years had 0.78 inch per day or less. Probability results show that this station has a $15.36 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in
winter precipitation intensity. Results show an increase of 0.005 inch of precipitation per precipitation day during the winter months (Table 5.95).

## Greenville

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Greenville are given in Tables 5.96, 5.97, 5.98, and 5.99. Greenville (Köppen climate classification Cfa ) receives an average of 42.72 inches of precipitation per year with most occurring during the spring months. Annually, this station receives an average of 58.75 days of precipitation, of which the largest portion occurs during the spring months. Annually, this station averages 0.73 inch per day with most occurring during the fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the spring months have the smallest amount of variability, while the winter is the most variable for precipitation days. The CV suggests that the winter months have the smallest amount of variability, while the spring months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and
precipitation intensity are less than their respective mean values, except for annual precipitation, and summer precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 29.50 inches. Ninety percent will be at or below 52.25 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 47.70 days. Ninety percent will be at or below 73.10 days, with $10 \%$ being above 73.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.61 inch per day. Ninety percent of the years had 0.85 inch per day or less. Probability results show that this station has a $16.09 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in fall total precipitation, and annual, summer, and winter precipitation intensity, and summer precipitation days. Results show an increase of 0.061 inch of fall total precipitation, with $7.7 \%$ of the variance accounted for by the regression. In addition, results show an increase of 0.002 inches of precipitation per precipitation day annually, with $9.1 \%$ of the variance accounted for by the regression. Results also show an increase of 0.004 precipitation per precipitation day for the summer, with $10.6 \%$ of the variance accounted for by the regression, and 0.006 inch per precipitation day during the winter months, with $14.6 \%$ of the variance accounted for by the regression (Table 5.100).

## Clarksville

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Clarksville are given in Tables 5.101, 5.102, 5.103, and 5.104. Clarksville (Köppen climate classification Cfa ) receives an average of 46.54 inches of precipitation per year, of which the largest portion occurs during the spring months. Annually, this station receives an average of 62.06 days of precipitation, most of which occurs during the spring months. Annually, this station averages 0.75 inch per day with most occurring during the fall months. A comparison of the CV suggests the winter months have the smallest amount of precipitation variability, while the summer is most variable. The CV suggests that the spring months have the smallest amount of variability, while the summer is the most variable for precipitation days. The CV suggests that the summer months have the smallest amount of variability, while the winter months are the most
variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for spring precipitation and precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 33.02 inches. Ninety percent will be at or below 59.84 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 49 days. Ninety percent will be at or below 77.20 days, with $10 \%$ being above 77.20 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.59 inch per day. Ninety percent of the years had 0.93 inch per day or less. Probability results show that this station has a $17.00 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in fall total precipitation, and fall precipitation intensity. Results show an increase of 0.095 inches of fall total precipitation per year, with $16.1 \%$ of the variance accounted for by the regression and an increase of 0.095 inch increase in precipitation per precipitation day, with $0.3 \%$ of the variance accounted for by the regression (Table 5.105).

## Marshall

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Marshall are given in Tables 5.106, 5.107, 5.108, and 5.109. Marshall (Köppen climate classification Cfa ) receives an average of 48.45 inches of precipitation per year with most occurring during the spring and winter months. Annually, this station receives an average of 66.10 days of precipitation, of which the largest portion occurs during the winter months. Annually, this station averages 0.74 inches per day with most occurring during the spring months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the summer are most variable. A comparison of the CV for precipitation days suggests the winter months have the smallest amount of variability, while the fall are most variable. The CV suggests that the spring months has the smallest amount of variability, while both the winter and summer months is the most variable for precipitation intensity. The median values of total
precipitation, precipitation days, and precipitation intensity is less than their respective mean values, except for annual and winter precipitation days and winter and fall precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 36.35 inches. Ninety percent will be at or below 63.50 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 53.10 days. Ninety percent will be at or below 83.10 days, with a $10 \%$ being above 83.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.62 inch per day. Ninety percent of the years had 0.86 inch per day or less. Probability results show that this station has an $18.11 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and winter total precipitation, and annual, summer, and winter precipitation intensity. Results show an annual increase of 0.115 inch in annual total precipitation, with $5.0 \%$ of the variance accounted for by the regression, and 0.072 inch increase in fall precipitation per year, with $10.7 \%$ of the variance accounted for by the regression. In addition, linear regression results show an increase of 0.003 inches of precipitation per precipitation day annually, with $32.2 \%$ of the variance accounted for by the regression, an increase of 0.004 inch of precipitation per precipitation day during both the summer and winter months, with $9.5 \%$ and 13.0 of the variance accounted for by the regression, respectively (Table 5.110).

## Summary for the Northeast region

Most precipitation and days with precipitation occur during the spring months for the Northeast stations. Precipitation intensity is greatest for most stations during the fall months. The spring months resulted in the least amount of variability for most stations for precipitation and precipitation days. Mixed results showed for precipitation intensity; the variability was low except during the fall months. Mixed results occurred seasonally for high variability for precipitation, precipitation days, and precipitation intensity. The highest probability for a rain day was $18.11 \%$ for Marshall. Most stations resulted in a positive skew for precipitation, precipitation days, and precipitation intensity. Median values fell less than the mean except for fall precipitation and winter and fall precipitation days for Mexia; spring precipitation days for Corsicana; annual precipitation and summer precipitation intensity for Greenville; spring precipitation and precipitation days for

Clarksville; and annual and winter precipitation days and winter and fall precipitation intensity for Marshall.

Total precipitation, precipitation days, and precipitation intensity annually and seasonally were grouped into equal frequency deciles. For the given stations, the bottom deciles included the $10 \%$ of events with the lowest values, while the top deciles include the $10 \%$ of events with the greatest value. Mexia showed the lowest values for precipitation and precipitation days with $10 \%$ of the years not exceeding 26.92 inches of precipitation and 41.70 days with precipitation. Corsicana resulted in the lowest values for precipitation intensity with $10 \%$ of the years not exceeding 0.56 inches per day. For Marshall, $10 \%$ of the years recorded exceeded 63.50 inches of precipitation and 83.10 days of precipitation. For Clarksville, $10 \%$ of the years exceeded 0.93 inch per day of precipitation.

There is a statistically significant increase in annual precipitation for Marshall, and an increase in precipitation for Greenville and Clarksville during the fall months. Mexia, Greenville, and Marshall resulted in an increase in annual precipitation intensity, while Mexia, Corsicana, Greenville, and Marshall resulted in an increase in precipitation intensity during the winter months. Clarksville resulted in an increase in fall precipitation intensity, while Greenville and Marshall resulted in an increase in summer precipitation intensity. There were no trends in precipitation days.

## Central Texas

In this region, the stations are all humid subtropical (Cfa) climate type. The Cfa climate has a bimodal precipitation pattern with May and September being the wettest months (Swanson 1995). Areas in this region classified as BSh represent a transition
between deserts to the west and humid climates to the east. The ten weather stations in this region include Lampasas (25), Temple (41), Llano (27), Blanco (6), Boerne (7), New Braunfels (34), San Antonio (38), Luling (28), Flatonia (20), and Hallettsville (23) (Figure 4.1).

## Lampasas

Lampasas is classified as a Cfa (humid subtropical) climate. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Lampasas are given in Tables $5.111,5.112,5.113$, and 5.114. Lampasas receives an average of 30.73 inches of precipitation per year with most occurring during the spring months. Annually, this station receives an average of 48.81 days of precipitation, of which the largest portion occurs during spring months. Annually, this station averages 0.62 inch per day with most occurring during the summer months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the fall months have the smallest amount of variability, while the winter is the most variable for precipitation days. The CV suggests that the spring months have the smallest amount of variability, while the summer months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual and summer precipitation days, and annual precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 18.55 inches. Ninety percent will be at or below 42.25 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 38.60 days. Ninety percent will be at or below
59.10 days, with $10 \%$ being above 59.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.49 inch per day. Ninety percent of the years had 0.75 inch per day or less. Probability results show that this station has a $13.37 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not indicate significant findings in regard to an increase or decrease in precipitation, precipitation days, or precipitation intensity during the period of record (Table 5.115).

## Temple

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Temple are given in Tables 5.116, 5.117, 5.118, and 5.119. Temple (Köppen climate classification Cfa) receives an average of 34.71 inches of precipitation per year with most occurring during the spring months. Annually, this station receives an average of 49.92 days of precipitation, of which the largest portion occurs during spring months. Annually, this station averages 0.70 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the both the summer and fall months are most variable. The CV suggests that the spring months are the smallest amount of variability, while the winter is the most variable for precipitation days. The CV suggests that the spring months have the smallest amount of variability, while the winter months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for summer precipitation, winter and spring precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 23.68 inches. Ninety percent will be at or below 46.66 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 37.80 days. Ninety percent will be at or below 61 days, with $10 \%$ being above 61.00 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.60 inch per day. Ninety percent of the years had 0.82 inch or less. Probability results show that this station has a $13.68 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show
significant findings in annual precipitation intensity with an increase of 0.001 inches of precipitation per precipitation day, with $8.6 \%$ of the variance accounted for by the regression (Table 5.120).

## Llano

Llano is classified as a Cfa (humid subtropical) climate. Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Llano are given in Tables 5.121, 5.122, 5.123, and 5.124. Llano receives an average of 27.35 inches of precipitation per year of which the largest portion occurs during the spring months. Annually, this station receives an average of 43.69 days of precipitation, most of which occurs during the spring months. Annually, this station averages 0.6303 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the spring months have the smallest amount of variability, while both the summer and fall months are the most variable for precipitation days. The CV suggests that the summer months have the smallest amount of variability, while the winter months are the most variable for
precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual, winter, and spring precipitation days, and summer and winter precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 18.30 inches. Ninety percent will be at or below 37.33 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 33.90 days. Ninety percent will be at or below 56.10 days, with $10 \%$ being above 56.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.53 inch per day. Ninety percent of the years had 0.74 inch per day or less. Probability results show that this station has an $11.96 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in winter precipitation intensity with an increase of 0.004 inches of precipitation per precipitation day, with $9.2 \%$ of the variance accounted for by the regression (Table 5.125).

## Blanco

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Blanco are given in Tables 5.126, 5.127, 5.128, and 5.129. Blanco (Köppen climate classification Cfa) receives an average of 34.62 inches of precipitation per year, of which the largest portion occurs during spring months. Annually, this station receives an average of 51.52 days of precipitation, most of which occurs during the spring months. Annually, this station averages 0.66 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the fall months have the smallest amount of variability, while the spring, summer, and winter are the most variable for precipitation days. The CV suggests that the spring months have the smallest amount of variability, while the winter months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values,
except for summer precipitation, summer and fall precipitation days, and spring precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 21.54 inches. Ninety percent will be at or below 46.01 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 38.90 days. Ninety percent will be at or below 66.10 days, with $10 \%$ being above 66.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.55 inch per day. Ninety percent of the years had 0.83 inch per day or less.

Probability results show that this station has a $14.11 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not show significant findings in total precipitation, precipitation days, or precipitation intensity (Table 5.130).

## Boerne

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Boerne are given in Tables 5.131, 5.132, 5.133, and 5.134. Boerne (Köppen climate classification Cfa) receives an average of 34.50 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 51.33 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.69 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the fall months have the smallest amount of variability, while the winter is the most variable for precipitation days. The CV suggests that the spring months have the smallest amount of variability, while the summer months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual and summer precipitation days, and spring and fall precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 20.59 inches. Ninety percent will be at or below 50.38 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 37.80 days. Ninety percent will be at or below 68 days, with $10 \%$ being above 68 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.51 inch per day. Ninety percent of the years had 0.85 inch per day or less. Probability results show that this station has a $14.06 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show
significant findings in annual and fall total precipitation, and annual, summer, and fall precipitation intensity. Results show an increase of 0.155 inch in annual total precipitation per year, with $8.0 \%$ of the variance accounted for by the regression, and 0.069 inch increase in fall precipitation per year, with $8.6 \%$ of the variance accounted for by the regression In addition, linear regression results show an increase of 0.003 inches of precipitation per precipitation day annually, with $14.3 \%$ of the variance accounted for by the regression, an increase of 0.010 inch of precipitation per precipitation day during the summer, with $13.9 \%$ of the variance accounted for by the regression, and 0.004 inch of precipitation per precipitation day during the fall months, with $9.7 \%$ of the variance accounted for by the regression (Table 5.135).

## New Braunfels

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for New Braunfels are given in Tables 5.136, 5.137, 5.138, and 5.139. New Braunfels (Köppen climate classification Cfa) receives an average of 34.20 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 48.58 days of precipitation, most of which occurs during the spring months. Annually, this station averages 0.71 inches of precipitation per day with most occurring during fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that both spring and fall months have the smallest amount of variability, while the winter is the most variable for precipitation days. The CV suggests that the spring months have the smallest amount of variability, while the summer months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual, spring, fall, and winter precipitation days, and annual precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 20.12 inches. Ninety percent will be at or below 48.68 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 35.90 days. Ninety percent will be at or below 61.10 days, with $10 \%$ being above 61.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.52 inch per day. Ninety percent of the years had 0.87 inch per day or less.

Probability results show that this station has a $13.31 \%$ chance that any one day in the year
would receive 0.1 mm of rain. Linear regression results do not show significant findings in total precipitation, precipitation days, or precipitation intensity (Table 5.140).

## San Antonio

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for San Antonio are given in Tables 5.141, 5.142, 5.143, and 5.144. San Antonio (Köppen climate classification Cfa) receives an average of 30.32 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 46.02 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.683 inch of precipitation per day with most occurring during the summer months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the summer months has the smallest amount of variability, while the winter is the most variable for precipitation days. The CV suggests that the summer months have the smallest amount of variability, while the winter months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their
respective mean values, except for annual precipitation, and spring precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 17.87 inches. Ninety percent will be at or below 42.75 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 31 days. Ninety percent will be at or below 59.10 days, with $10 \%$ being above 59.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.53 inch per day. Ninety percent of the years had 0.89 inch per day or less. Probability results show that this station has a $12.60 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual total precipitation, and summer precipitation days. Results show an annual increase of 0.108 inch in annual total precipitation, with $5.8 \%$ of the variance accounted for by the regression and a 0.073 increase in precipitation days per year during the summer months, with $10.3 \%$ of the variance accounted for by the regression (Table 5.145).

## Luling

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Luling are given in Tables 5.146, 5.147, 5.148, and 5.149. Luling (Köppen climate classification Cfa) receives an average of 35.04 inches of precipitation per year with most occurring during the fall months. Annually, this station receives an average of 51.52 days of precipitation, of which the largest portion occurs during the fall months. Annually, this station averages 0.69 inch of precipitation per day with most occur during the fall months. A comparison of the CV suggests the summer months have the smallest amount of precipitation variability, while the winter is most variable. The CV suggests that the summer months have the smallest amount of variability, while both the spring and fall are the most variable for precipitation days. The CV suggests that the fall months have the smallest amount of variability, while both the spring and summer months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective
mean values, except for fall and winter precipitation days, and fall precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 22.21 inches. Ninety percent will be at or below 47.89 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 36.80 days. Ninety percent will be at or below 62.50 days, with $10 \%$ being above 62.50 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.53 inch per day. Ninety percent of the years had 0.89 inch per day or less. Probability results show that this station has a $14.11 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings with an increase of 0.062 inch of fall total precipitation per year, with $6.1 \%$ of the variance accounted for by the regression (Table 5.150).

## Flatonia

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Flatonia are given in Tables $5.151,5.152,5.153$, and 5.154. Flatonia (Köppen climate classification Cfa) receives an average of 37.68 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 53.96 days of precipitation, most of which occurs during the winter months. Annually, this station averages 0.71 inch of precipitation per day, with most occurring during the fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the fall is most variable. The CV suggests that the fall months have the smallest amount of variability, while the spring is the most variable for precipitation days. The CV suggests that the spring months have the smallest amount of variability, while the summer months are the most variable for precipitation intensity. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual precipitation, and fall, and spring precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 24.09 inches. Ninety percent will be at or below 53.60 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 39.90 days. Ninety percent will be at or below 68.10 days, with $10 \%$ being above 68.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.56 inch per day. Ninety percent of the years had 0.87 inch per day or less. Probability results show that this station has a $14.78 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression
results do not show significant findings in total precipitation, precipitation days, or precipitation intensity (Table 5.155 ).

## Hallettsville

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Hallettsville are given in Tables 5.156, 5.157, 5.158, and 5.159. Hallettsville (Köppen climate classification Cfa) receives an average of 39.42 inches of precipitation per year, of which the largest portion occurs during the spring months. Annually, this station receives an average of 55.33 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.73 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests the spring months have the smallest amount of precipitation variability, while the summer is most variable. The CV suggests that the fall months have the smallest amount of variability, while the summer is the most variable for precipitation days. The CV suggests that the winter months have the smallest amount of variability, while the fall months are the most variable for precipitation intensity. The median values of total precipitation, precipitation
days, and precipitation intensity are less than their respective mean values, except for annual and fall precipitation, winter and fall precipitation days, and spring precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 25.26 inches. Ninety percent will be at or below 53.80 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 39.90 days. Ninety percent will be at or below 70 days, with a $10 \%$ being above 70 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.60 inch per day. Ninety percent of the years had 0.89 inch per day or less. Probability results show that this station has a $15.15 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in fall total precipitation with an increase of 0.072 inches, with $7.7 \%$ of the variance accounted for by the regression (Table 5.160).

## Summary for the Central Texas Region

Most precipitation and days with precipitation occur during the spring and fall months for the Central Texas stations. Precipitation is greatest during the fall months except for Lampasas, Boerne, and San Antonio. The majority of the stations showed the least amount of variability for precipitation during the spring months. A majority of stations resulted in low variability during the spring months for precipitation intensity. Variability for precipitation was highest during the winter months for a majority of the stations and highest for precipitation days during the fall months. High variability occurred between summer, winter, and fall months for precipitation intensity for the Central Texas stations. The highest probability of a rain day resulted in $15.15 \%$ for Hallettsville. Median values fell below the mean except for annual and summer precipitation days and annual precipitation intensity for Lampasas; summer precipitation, and winter and spring precipitation days for Temple; annual, winter, and spring
precipitation days, and summer and winter precipitation intensity for Llano; summer precipitation, summer and fall precipitation days, and spring precipitation intensity for Blanco; annual and summer precipitation days, and spring and fall precipitation intensity for Boerne; annual, spring, and fall precipitation days, and annual precipitation intensity for New Braunfels; annual precipitation and spring precipitation days for San Antonio, fall and winter precipitation days and fall precipitation intensity for Luling; annual precipitation and fall and spring precipitation days for Flatonia; and annual and fall precipitation, winter and fall precipitation days, and spring precipitation intensity for Hallettsville.

Total precipitation, precipitation days, and precipitation intensity annually and seasonally were grouped into equal frequency deciles. For the given stations, the bottom deciles included the $10 \%$ of events with the lowest values, while the top deciles include the $10 \%$ of events with the greatest value. San Antonio resulted in the lowest values for precipitation and precipitation days with $10 \%$ of the years not exceeding 17.87 inches of precipitation and 31.00 days with precipitation. Boerne resulted in the lowest values for precipitation intensity with $10 \%$ of the years not exceeding 0.51 inch of precipitation per day. For Hallettsville, $10 \%$ of the years on record exceeded 53.80 inch of precipitation and 0.89 inch of precipitation per day. For San Antonio and Luling, $10 \%$ of the years on record exceeded 0.89 inch of precipitation per day, while Flatonia exceeded 68.10 precipitation days. There is a statistically significant increase in annual precipitation for Bourne and San Antonio, while Bourne, Luling, and Hallettsville show an increase in fall precipitation over the period of record. San Antonio is the only station to show an increase in precipitation days during the summer months during the period of record.

There is an increase in annual precipitation intensity for Temple and Boerne, while Llano resulted in an increase in winter precipitation intensity. Boerne resulted in an increase in fall and summer precipitation intensity, while there were no stations that resulted in an increase or decrease in spring precipitation intensity.

## Southeast

The southeast region is classified as subtropical with hot, humid summers. In this region, there is one distinct climate type based on the Köppen climate classification; Cfa (humid subtropical). This region receives humid tropical air from the Gulf of Mexico during the summer, and cyclonic storms during the winter months. The three weather stations in this region include Brenham (8), Danevang (14), and Liberty (26) (Figure 5.1).

## Brenham

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Brenham are given in Tables 5.161, 5.162, 5.163, and 5.164. Brenham (Köppen climate classification Cfa ) receives an average of 41.96 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 59.50 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.72 inch of precipitation per day with most occur during the fall months. A comparison of the CV suggests that the spring months have the smallest amount of precipitation variability, while fall is the most variable. For precipitation days, the CV suggests that the fall months have the least variability, while the summer is the most variable. The winter months show the smallest amount of variability in precipitation intensity, while spring is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less
than their respective mean values, except for annual and summer precipitation days, and annual and winter precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 28.50 inches. Ninety percent will be at or below 56.47 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 43.80 days. Ninety percent will be at or below 72.50 days, with $10 \%$ being above 69 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.56 inch per day. Ninety percent of the years had 0.89 inch per day or less. Probability results show that this station has a $16.30 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and fall total precipitation. Results show an increase of 0.143 inch per year in annual total precipitation, with $7.5 \%$ of the variance accounted for by the regression, and 0.117 inch per year increase in fall precipitation, with $15.6 \%$ of the variance accounted for by the regression (Table 5.165).

## Danevang

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Danevang are given in Tables 5.166, 5.167, 5.168, and 5.169. Danevang (Köppen climate classification Cfa ) receives an average of 41.62 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 58.54 days of precipitation, most of which occurs during the summer months. Annually, this station averages 0.73 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests that the spring months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the summer months have the least variability, while the spring is the most variable. The spring months show the smallest amount of variability in precipitation intensity, while winter is the most variable.

The median values of total precipitation, precipitation days, and precipitation intensity
are less than their respective mean values, except for spring precipitation, and spring and fall precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 29.13 inches. Ninety percent will be at or below 56.69 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 45.70 days. Ninety percent will be at or below 70.10 days, with $10 \%$ being above 70.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.55 inch per day. Ninety percent of the years had 0.93 inch per day or less. Probability results show that this station has a $16.03 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and fall total precipitation, and annual, spring, summer, fall, and winter precipitation days. Results show an increase of 0.164 inches per year in annual total precipitation, with $9.4 \%$ of the variance accounted for by the regression, and a 0.090 inch per year increase in fall precipitation, with $10.1 \%$ of the variance accounted for by the regression. For precipitation days, linear regression results shows an increase of 0.201 days per year increase annually, with $9.7 \%$ of the variance accounted for by the regression. Results also show 0.370 days per year increase for precipitation days during the summer months, with $1.8 \%$ of the variance accounted for by the regression, 0.156 days per year increase in precipitation days during the fall months, with $4.3 \%$ of the variance accounted for by the regression, and 0.348 days per year increase in precipitation days during the winter months, with $1.9 \%$ of the variance accounted for by the regression (Table 5.170).

## Liberty

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Liberty are given in Tables $5.171,5.172,5.173$, and 5.174. Liberty (Köppen climate classification Cfa) receives an average of 54.75 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 71.90 days of precipitation, most of which occurs during the summer months. Annually, this station averages 0.78 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests that the winter months have the smallest amount of precipitation variability, while fall is the most variable. For precipitation days, the CV suggests that the winter months have the least variability, while the spring is the most variable. The summer months show the smallest amount of variability in precipitation intensity, while fall is the most variable. The data shows that over the period of record, $50 \%$ of the total precipitation, precipitation days, and precipitation intensity are below their respective mean values except for annual and
summer precipitation days, and annual precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 37.97 inches. Ninety percent will be at or below 70.08 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 56 days. Ninety percent will be at or below 89.10 days, with 10 \% being above 89.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.59 inch per day. Ninety percent of the years had 0.95 inch per day or less. Probability results show that this station has a $19.69 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and fall total precipitation, and annual precipitation intensity. Results show an increase of 0.221 inch per year in annual total precipitation, with $11.9 \%$ of the variance accounted for by the regression. In addition, results show a 0.132 inch per year increase in fall precipitation, with $15.8 \%$ of the variance accounted for by the regression. In addition, linear regression results show an increase of 0.004 inch of precipitation per precipitation day on an annual basis, with $18.4 \%$ of the variance accounted for by the regression (Table 5.175).

## Summary for the Southeast Region

Most precipitation occurs during the fall months, while the majority of precipitation days occur during the summer months. Precipitation intensity is highest for the majority of stations during the fall months. A majority of the stations showed the least amount of variability for precipitation during the spring months, while results were mixed between spring, summer, fall and winter for precipitation days and intensity. A majority of the stations showed the highest amount of variability during the fall months for precipitation, and the spring months for precipitation days. The highest probability of a rain day was $19.69 \%$ for Liberty. All other stations fell below this value. Most stations resulted in a positive skew for precipitation, precipitation days, and precipitation intensity. Median values fell less than the mean except for annual and summer precipitation days and annual and winter precipitation intensity for Brenham; spring
precipitation, and spring and fall precipitation days for Danevang; and annual and summer precipitation days, and annual precipitation intensity for Liberty.

Total precipitation, precipitation days, and precipitation intensity annually and seasonally were grouped into equal frequency deciles. For the given stations, the bottom deciles included the $10 \%$ of events with the lowest values, while the top deciles include the $10 \%$ of events with the greatest value. Brenham resulted in the lowest values for precipitation and days with precipitation with $10 \%$ of the years not exceeding 28.50 inches of precipitation and 43.80 days with precipitation. Danevang resulted in the lowest values for precipitation intensity with $10 \%$ of the year not exceeding 0.55 inch of precipitation per day. For Liberty, $10 \%$ of the years on record exceeded 70.08 inch of precipitation, 89.10 precipitation days, and 0.95 inch of precipitation per day.

There is a statistically significant increase for all stations in annual precipitation and fall precipitation. Danevang shows an increase in annual, winter, fall, summer, and spring precipitation days, while Liberty resulted in an increase in annual precipitation intensity.

## South

In this region, there are two distinct climate types based on the Köppen climate classification; Cfa (humid subtropical) and BSh (subtropical semi-arid hot steppe). Areas in this region experience hot summers and dry winters (Swanson 1995). The Cfa climate humid subtropical with warm summers is controlled by proximity to the Gulf of Mexico. During the winter, this region can be affected by strong polar air masses and is also subjected to occasional tropical disturbances during the summer and fall months. The
seven weather stations in this region include Eagle Pass (16), Encinal (18), Beeville (5), Alice (2), Corpus Christi (11), Falfurrias (19), and Rio Grande City (37) (Figure 5.1).

## Eagle Pass

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Eagle Pass are given in Tables 5.176, 5.177, 5.178, and 5.179. Eagle Pass (Köppen climate classification BSh ) receives an average of 20.63 inches of precipitation per year, of which the largest portion occurs during the summer months. Annually, this station receives an average of 32.10 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.66 inch of precipitation per day with most occur during the summer months. A comparison of the CV suggests that the fall months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the fall months have the least variability, while the winter is the most variable. The fall months show the smallest amount of variability in precipitation intensity, while winter is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for summer precipitation days and summer precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 12.18 inches. Ninety percent will be at or below 31.63 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 22.80 days. Ninety percent will be at or below 43.60 days, with $10 \%$ being above 43.60 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.46 inch per day. Ninety percent of the years had 0.88 inch per day or less.

Probability results show that this station has an $8.79 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and spring precipitation intensity. Results show a decrease of 0.002 inch per precipitation day, with $8.1 \%$ of the variance accounted for by the regression, and a decrease of 0.007 inch per precipitation day in spring precipitation intensity, with $12.1 \%$ of the variance accounted for by the regression.

## Encinal

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Encinal are given in Tables 5.181, 5.182, 5.183, and 5.184. Encinal (Köppen climate classification BSh ) receives an average of 21.35 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 29.48 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.76 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests that both the spring and summer months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the fall months have the least variability, while the winter is the most variable. The fall months show the smallest amount of variability in precipitation intensity, while winter is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for fall precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 13.72 inches. Ninety percent will be at or below 31.92 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 17 days. Ninety percent will be at or below 43 days, with $10 \%$ being above 43 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.52 inch per day. Ninety percent of the years had 1.11 inch per day or less. Probability results show that this station has an $8.07 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual, fall, and winter precipitation days, and annual
precipitation intensity. Results show a decrease of 0.35 precipitation days annually, with $25.6 \%$ of the variance accounted for by the regression, and a decrease of 0.107 days during the fall months, with $13.4 \%$ of the variance accounted for by the regression. Results also show a decrease of 0.184 days during the winter months, with $41.4 \%$ of the variance accounted for by the regression. In addition, linear regression results show an annual increase of 0.0094 inch in precipitation per precipitation day, with $29.3 \%$ of the variance accounted for by the regression, and a 0.019 inch increase in precipitation per precipitation day during the winter months with $9.6 \%$ of the variance accounted for by the regression (Table 5.185).

## Beeville

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Beeville are given in Tables 5.186, 5.187, 5.188, and 5.189. Beeville (Köppen climate classification Cfa) receives an average of 31.21 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 46.96 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.69 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the fall months have the least variability, while the winter is the most variable. The winter months show the smallest amount of variability in precipitation intensity, while fall is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual precipitation, and summer precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 18.63 inches. Ninety percent will be at or below 43.26 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 36.90 days. Ninety percent will be at or below 60.10 days, with a $10 \%$ being above 60.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.52 inch per day. Ninety percent of the years had 0.89 inch per day or less. Probability results show that this station has a $12.87 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in fall
and winter precipitation days. There is a decrease of 0.107 precipitation days during the fall months, with $4.3 \%$ of the variance accounted for by the regression (Table 5.190).

#### Abstract

Alice Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Alice are given in Tables 5.191, 5.192, 5.193, and 5.194. Alice (Köppen climate classification Cfa) receives an average of 27 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 39.23 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.72 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests that the fall months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the summer months have the least variability, while the winter is the most variable. The spring months show the smallest amount of variability in precipitation intensity, while summer is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than

their respective mean values, except for annual precipitation days. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 16.95 inches. Ninety percent will be at or below 39.49 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 24.90 days. Ninety percent will be at or below 51.10 days, with $10 \%$ being above 51.10 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.52 inch per day. Ninety percent of the years had 0.96 inch per day or less. Probability results show that this station has a $10.74 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual and fall precipitation days, and annual and fall precipitation intensity. Results show a decrease of 0.25 days per year with $13.3 \%$ of the variance accounted for by the regression, and a decrease of 0.17 days per year during the fall months, with $27.4 \%$ of the variance accounted for by the regression. Additionally, results show an increase of .0049 inch of precipitation per precipitation day on an annual basis, with $13.3 \%$ of the variance accounted for by the regression, and an increase of .014 inches of precipitation per precipitation day during the fall months, with $17.8 \%$ of the variance accounted for by the regression (Table 5.195).

## Corpus Christi

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Corpus Christi are given in Tables 5.196, 5.197, 5.198, and 5.199. Corpus Christi (Köppen climate classification Cfa) receives an average of 29.93 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 43.00 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.72 inch of precipitation per day with most occurring during the spring months. A comparison of the CV suggests that the fall months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the fall months have the least variability, while the spring is the most variable. The fall months show the smallest amount of variability in precipitation intensity, while spring is the most variable. The
median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values, except for annual and summer precipitation days and annual precipitation intensity. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 19.37 inches. Ninety percent will be at or below 41.50 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 31 days. Ninety percent will be at or below 56 days, with $10 \%$ being above 56 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.54 inch per day. Ninety percent of the years had 0.87 inch per day or less. Probability results show that this station has an $11.78 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results show significant findings in annual total precipitation with an increase of 0.099 inch per year, with $6.0 \%$ of the variance accounted for by the regression (Table 5.200).

## Falfurrias

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Falfurrias are given in Tables 5.201, 5.202, 5.203, and 5.204. Falfurrias (Köppen climate classification Cfa) receives an average of 25.05 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 39.92 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.67 inch of precipitation per day with most occurring during the spring months. A comparison of the CV suggests that the spring months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the fall months have the least variability, while the winter is the most variable. The spring months show the smallest amount of variability in precipitation intensity, while summer is the most variable. The median values of total precipitation, precipitation days, and precipitation intensity are less than their respective mean values. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 16.27 inches. Ninety percent will be at or below 36.58 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 27 days. Ninety percent will be at or below 50 days, with $10 \%$ being above 50 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.47 inch per day. Ninety percent of the years had 0.88 inch per day or less. Probability results show that this station has a $10.38 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not show significant findings in total precipitation, precipitation days, or precipitation intensity (Table 5.205).

## Rio Grande City

Descriptive statistics for total precipitation, precipitation days, and precipitation intensity for Rio Grande City are given in Tables 5.206, 5.207, 5.208, and 5.209. Rio Grande City (Köppen climate classification BSh) receives an average of 19.73 inches of precipitation per year, of which the largest portion occurs during the fall months. Annually, this station receives an average of 32.02 days of precipitation, most of which occurs during the fall months. Annually, this station averages 0.66 inch of precipitation per day with most occurring during the fall months. A comparison of the CV suggests that the summer months have the smallest amount of precipitation variability, while winter is the most variable. For precipitation days, the CV suggests that the summer months have the least variability, while the winter is the most variable. The summer months show the smallest amount of variability in precipitation intensity, while winter is the most variable. The median values of total precipitation, precipitation days, and
precipitation intensity are less than their respective mean values. The results show that for $10 \%$ of the years on record, total annual precipitation will be at or below 11.99 inches. Ninety percent will be at or below 30.40 inches, with $10 \%$ above this value. For precipitation days, results show that for $10 \%$ of the years on record, annual number of days will be at or below 21.00 days. Ninety percent will be at or below 42.40 days, with $10 \%$ being above 42.40 days. For precipitation intensity, results show that $10 \%$ of the years on record experienced at or below 0.47 inch per day. Ninety percent of the years had 0.86 inch per day or less. Probability results show that this station has an $8.77 \%$ chance that any one day in the year would receive 0.1 mm of rain. Linear regression results do not show significant findings in total precipitation, precipitation days, or precipitation intensity (Table 5.210).

## Summary for the South Region

Most precipitation, days with precipitation, and precipitation intensity occur during the fall months. A majority of the stations showed the least amount of variability during the fall months for precipitation and days with precipitation. High variability occurred during the winter months for precipitation and days with precipitation. The highest probability of a rain day was in $12.87 \%$ for Beeville. Most stations resulted in a positive skew for precipitation, precipitation days, and precipitation intensity. Median values fell less than the mean except for summer precipitation days and summer precipitation intensity for Eagle Pass; fall precipitation days for Encinal; annual precipitation and summer precipitation days for Beeville; annual precipitation days for Alice; and annual and summer precipitation days and annual precipitation intensity for Corpus Christi.

Total precipitation, precipitation days, and precipitation intensity annually and seasonally were grouped into equal frequency deciles. For the given stations, the bottom deciles included the $10 \%$ of events with the lowest values, while the top deciles include the $10 \%$ of events with the greatest value. Rio Grande City resulted in the lowest value for precipitation with $10 \%$ of the years not exceeding 11.99 inches of precipitation. Encinal resulted in the lowest values for precipitation days with $10 \%$ of the years not exceeding 17 days of precipitation and Eagle Pass with 0.46 inch of precipitation per day. For Beeville, $10 \%$ of the years on record exceeded 43.26 inches of precipitation and 60.10 days of precipitation. Results also showed that $10 \%$ of the years exceeded 1.11 inches of precipitation per day for Encinal.

There is a statistically significant increase in annual precipitation for Corpus Christi. Encinal and Alice resulted in a decrease in annual precipitation days, while Encinal and Beeville resulted in a decrease in winter precipitation days. Encinal, Beeville, and Alice resulted in a decrease in fall precipitation days. Eagle Pass resulted in a decrease in annual precipitation intensity, while Encinal and Alice resulted in an increase in annual precipitation intensity. Alice resulted in an increase in fall precipitation intensity, while Eagle Pass showed a decrease in spring precipitation intensity.

## CHAPTER 6

## DISCUSSION OF TRENDS

The purpose of this study was to identify trends in annual and seasonal precipitation at 42 weather stations in Texas to determine if areas around the state are becoming increasingly wet or dry. This chapter presents a discussion of the results from chapter five using a series of maps for annual and seasonal precipitation, precipitation days, precipitation intensity, probability of a rain day, and precipitation variability. The maps were developed using the ArcMap program and illustrate the significant decadal trends. Numeric values indicated on the map depict whether trends are increasing or decreasing at the stations. Stations that do not have values on the maps imply that no trend exists during the period of record. The probability maps illustrate the probability that any day will receive precipitation. A table indicating trends in precipitation, precipitation days, and precipitation intensity are presented in Table 6.1 for all stations annually and seasonally.

## Annual

Figures 6.1, 6.2, and 6.3 show the linear regression results for annual total precipitation, precipitation days and precipitation intensity over the reference period 1932-2002. Overall, linear regression results suggest there has been a positive trend in annual total precipitation for several stations in the eastern half of the state, with no
change for stations in the western half. An increase in precipitation days was found for one station in southeast Texas, and a decrease in the number of days for two stations in south Texas. There were no significant trends in precipitation days for the rest of the stations in the state. Changes in the amount of total precipitation can be caused directly by changes in the number of precipitation events, by the amount of precipitation occurring in each event, or a combination of both. The effects are a result of the sequence of synoptic conditions influencing the particular area (Robinson 2007).

Annual precipitation intensity increased for several stations in the eastern half of the state, while a decrease was found for only one station (i.e. Eagle Pass) in the south region of the state. There were no changes in precipitation intensity for stations in the Panhandle. Ft. Stockton was the only station in west Texas that showed an increase in precipitation intensity, while there were no changes in total precipitation or days with precipitation. In general, positive trends in annual precipitation and precipitation intensity resulted largely for stations in the eastern half of the state. Interestingly, Danevang is the only station in the southeast that is increasing in both annual total precipitation and the number of days with precipitation. Located near the Gulf of Mexico, Danevang is subjected to tropical activity during the late spring to fall months, as well as air mass (convective) thunderstorms, and frontal storms in the cooler months (Bomar 1999). The results suggest that precipitation from these events are occurring more frequently given that Danevang has shown an increase in 2.01 days with precipitation, and 1.64 inches of precipitation per decade during the period of record. Liberty, located in southeast Texas resulted both in an increase in annual precipitation intensity and annual total precipitation. This station is receiving greater precipitation and
more precipitation despite no change in the number of days with precipitation.
Precipitation associated with a slow-moving upper atmospheric storm system or the remains of a stalled tropical storm system can create an increase in total precipitation and intensity. In addition, when warm, moist Gulf air is fed into a stalled large-scale weather system, heavy or intense precipitation can result as well (Bomar 1999). While both Alice and Encinal in south Texas are decreasing in annual precipitation days, results reveal that there is no change in total precipitation. However, there is an increase in precipitation intensity at these stations. The stations are receiving more precipitation on days that it does rain. The neighboring station in Corpus Christi shows an increase in total precipitation but no statistically significant change in the number of days or precipitation intensity for the period of record.

Figure 6.1. Annual Precipitation, Change per Decade, 1932-2002

Figure 6.2. Annual Precipitation Days Change per Decade, 1932-2002

Figure 6.3. Annual Precipitation Intensity Change per Decade, 1932-2002

## Spring

Figures $6.4,6.5$, and 6.6 show the linear regression results for spring total precipitation, precipitation days, and precipitation intensity over the reference period 1932 - 2002. There were no significant trends found for total precipitation or precipitation days for the spring months. Two significant trends were found for precipitation intensity. An increase in spring precipitation intensity resulted for the Brownwood station in north central Texas, while a decrease in precipitation intensity occurred for the Eagle Pass station in South Texas. The Brownwood station is subjected to contrasting air masses associated with frontal activity during the spring months, which can produce higher amounts of rainfall in short periods of time.

Figure 6.4. Spring Precipitation Change per Decade, 1932-2002

Figure 6.5. Spring Precipitation Days Change per Decade, 1932-2002

Figure 6.6. Spring Precipitation Intensity Change per Decade, 1932-2002

#### Abstract

Summer

Figures 6.7, 6.8, and 6.9 show the linear regression results for summer total precipitation, precipitation days, and precipitation intensity over the reference period 1932 - 2002. An increase in summer precipitation resulted for the station in Dublin in north central Texas, while no other changes occurred for the rest of the state. Precipitation days increased for the station in McCamey in west Texas, and the station in San Antonio in Central Texas. Summer precipitation intensity increased for five stations in north central, northeast, and central Texas. Convective storms are common during the summer months, which may be a contributing factor to the positive trend in precipitation intensity. Dublin was the only weather station that resulted in an increase in both summer total precipitation and precipitation intensity. Dublin is receiving more precipitation on days that it does rain during the summer months.

Figure 6.7. Summer Precipitation Change per Decade, 1932-2002

Figure 6.8. Summer Precipitation Days Change per Decade, 1932-2002

Figure 6.9. Summer Precipitation Intensity Change per Decade, 1932-2002

## Fall

Figures $6.10,6.11$, and 6.12 show the linear regression results for fall total precipitation, precipitation days, and precipitation intensity over the reference period 1932 - 2002. An increase in fall precipitation was significant for stations in the eastern half of the state, while no changes resulted for stations in the south, the west, and the northern-most regions of the state. The number of days with fall precipitation decreased for Encinal in south Texas, but stayed the same for total precipitation. Encinal is receiving more precipitation on days that it does rain during the fall months. Fall precipitation intensity increased for the station in Boerne in central Texas, and Alice in south Texas, but decreased in Haskell in north central Texas. Boerne was the only station that showed both an increase in fall precipitation and precipitation intensity for the period of record. This trend indicates that this station is receiving more precipitation on days that it does rain. A contributing factor is due to frontal and tropical activity common to the region during the fall months. Orographic enhancement of precipitation from the Balcones Escarpment may also be a factor for an increase in precipitation and precipitation intensity for the station in Boerne.

Figure 6.11. Fall Precipitation Days Change per Decade, 1932-2002

Figure 6.12. Fall Precipitation Intensity Change per Decade, 1932-2002

## Winter

Figures 6.13. 6.14, and 6.15 show the linear regression results for winter total precipitation, precipitation days, and precipitation intensity over the reference period 1932-2002. For the winter months, a decrease in precipitation days occurred for the station in Encinal in south Texas, while no other changes were noted for the rest of the state during the winter months. Winter precipitation intensity increased for stations in the northeast, north central, the Panhandle, and southeast regions of the state. This trend indicates that more precipitation is occurring per event although the number of days is staying the same. No trends were noted for precipitation intensity for the south and western regions of the state. Frontal activity is the dominant weather phenomenon in Texas during the winter months and may be a factor for the increase in precipitation intensity.

Figure 6.13. Winter Precipitation Change per Decade, 1932-2002

Figure 6.14. Winter Precipitation Days Change per Decade, 1932-2002

Figure 6.15. Winter Precipitation Intensity Change per Decade, 1932-2002

## Probability

Figures $6.16,6.17,6.18,6.19$, and 6.20 show the annual and seasonal probability of a day with precipitation over the reference period 1932 - 2002. Annual probability of a day with precipitation was highest in the east and lowest in the west. This makes sense because climatologically, the eastern section of the state receives higher amounts of precipitation annually than locations in the western section of the state. Spring probability statistics reveal higher values in northeast Texas and lower values in the south and west. Precipitation associated with frontal activity is common in the northeast during the spring months, which could be a contributing factor to the higher probability values in this region as opposed to the west and southern reaches of the state. Summer probability statistics reveal higher values overall for stations in southeast Texas during the summer months. Probability values for the rest of the state are fairly uniform with south Texas having the lowest values. Summer precipitation in Texas, except for west Texas, is often dictated by the degree of activity or inactivity of tropical weather systems in the Gulf of Mexico (Bomar 1999). Higher probability values for stations in southeast Texas is related to persistent flow from the Gulf of Mexico that is common to this region during the summer months.

Fall probability statistics reveal higher values for days with fall precipitation for stations in southeast Texas, and lower values for stations in the west Texas. During the fall months, the North American monsoon rains typically do not influence west Texas past the month of September. The higher probability values for the southeast stations may be associated with tropical activity from the Gulf of Mexico that is common during the fall months. Winter probability statistics reveal high values in the southeast and
northeast regions, and low values in the west. Again, frontal activity may be associated with the higher probability values in the southeast and northeast regions of the state.

Figure 6.19. Fall Probability of a Day with Precipitation, 1932-2002

Figure 6.20. Winter Probability of a Day with Precipitation, 1932-2002

## Variability

Figures $6.21,6.22,6.23,6.24$, and 6.25 show the coefficient of variation of annual and seasonal precipitation over the reference period 1932 - 2002. Variability in annual precipitation was lowest for southeast Texas while stations in west Texas experience a higher variability. Precipitation in arid environments such as in west Texas is subject to short pulses of precipitation events, which could be a contributory factor for the higher variability in annual precipitation. The area is also influenced by the North American monsoon (NA monsoon), also known as the Southwest United States monsoon. The NA monsoon is associated with the high pressure that moves northward toward southern Utah and Colorado during the summer months creating an easterly to southeasterly flow aloft, and a low pressure which develops from surface heating over the Southwest United States (Adams 2003). Pulses of low-level moisture are transported from the Gulf of California and upper level moisture is transported from the Gulf of Mexico by easterly winds aloft to this region (Adams 2003). This phenomenon brings a pronounced increase in precipitation from July to mid-September over a large area of the southwestern United States. Locations affected by the NA monsoon receive at least $50 \%$ of its annual precipitation in July, August, and September (Adams 2003). West Texas lies climatologically on the fringes of this phenomenon and this is a contributing factor to the high variability in annual precipitation in west Texas.

Spring precipitation was more variable for stations in the western region compared to stations in other regions around the state. Again, west Texas is subject to short pulses of heavy rainfall, which could be a contributing factor for the higher variability in spring precipitation, especially as frontal systems impact the region.

Further, orographic enhancement of precipitation from air masses coming from the north, the Pacific Ocean, and Gulf of Mexico can create a higher variability in precipitation for these stations in west Texas during the spring months.

During the summer months, the difference in variability across the state is not large. Precipitation is more variable for stations in west, north central, central, and south Texas, and less variable in the Panhandle, northeast, and southeast Texas.

Variability of fall precipitation reveals higher values in west Texas, while all other values around the state are fairly uniform. Winter precipitation is most variable for stations in the west and south regions, and lower in the northeast and southeast regions of the state. As stated above, west Texas is subject to short pulses of heavy rainfall, which could be a contributing factor for the higher variability in winter precipitation. In addition, orographic enhancement of precipitation can create a higher variability in precipitation for these stations in west Texas during the winter months.

## Summary of Trend Results

Table 6.1 shows the results of the application of the linear regression test to detect trends for total precipitation, precipitation days, and precipitation intensity for all stations annually and seasonally over the referenced period 1932 - 2002. The trends in the table are expressed as either up-arrows, illustrating an increasing trend, or down-arrows, showing a decreasing trend. A dashed line indicates no trend during the referenced period of 1932-2002. For total precipitation, increasing trends annually and during the fall months are most notable for some stations in the southeast, central, and northeast locations. A decrease in annual, fall, and winter precipitation days has been detected mostly for stations in south Texas. There is an increase in precipitation intensity annually and during the summer, fall, and winter months for some stations in the north central, northeast, central, and south Texas. Although, an increase or decrease of precipitation trends is most notable for selected stations in the eastern half of the state, in terms of all stations, very few trends in precipitation, precipitation days, and precipitation intensity were found in this study.

## CHAPTER 7

## SUMMARY OF RESEARCH AND FINDINGS

Through a series of statistical analysis techniques, this study improves our knowledge regarding the spatial and temporal precipitation trends in Texas from 1932 2002. This research builds upon previous studies on precipitation in Texas and also offers a statistical method to examine precipitation trends in other regions. The main purpose of this work was to present an analysis of annual and seasonal precipitation for 42 stations across Texas during the period of record. The relative dearth of research on precipitation trends in Texas led to my primary objectives:

- The first objective was to identify the temporal patterns of annual and seasonal precipitation from 1932-2002. More specifically, was the total annual and seasonal precipitation, precipitation days, and precipitation intensity increasing, decreasing, or staying steady at each station during the period of record?
- The second objective was to examine the spatial patterns of precipitation across the state for the period of record.
- The third objective was to examine the variability expressed as dry and moist periods for the state.

Linear regression results showed positive trends in annual total precipitation for several stations in the eastern half of the state during the period of record. All stations in the southeast region showed positive trends during the period of record. While a large
portion of stations in the eastern half of the state revealed positive trends in annual precipitation intensity, only one station in the south region resulted in a decrease in intensity. Two stations in the south showed an increase in precipitation intensity as well as a decrease in the number of days with precipitation on an annual basis. At these stations, more precipitation per event occurred despite the decrease in number of precipitation days.

The spring months did not reveal any trends or changes in total precipitation or days with precipitation spatially or temporally. The spring months resulted in a negative trend for precipitation intensity for one station in the south, and a positive trend for one station in the north central region. Precipitation intensity during the summer months revealed an increase for selected stations in the northern half of the state, while there were no changes in the number of days with precipitation at these stations. Convective and tropical storms affect these regions during the summer months, which may be a contributing factor to the positive trend in precipitation intensity at these stations.

The fall months revealed positive trends in total precipitation for various stations in the eastern to the northeastern half of the state. A contributing factor may be due to frontal and tropical activity common to the region during the fall months. There were no trends or changes during the period of record for fall total precipitation for stations in the west, the Panhandle, and south regions. One station in central Texas revealed both an increase in fall precipitation and precipitation intensity for the period of record. Along with frontal and tropical activity, orographic enhancement of precipitation was a factor for an increase in precipitation and precipitation intensity.

Winter precipitation intensity increased for various stations in the northeast, north central, Panhandle, and southeast regions of the state, while there were no changes in total precipitation or days with precipitation. New et al. (2001) noted similar results from studies that have identified an increase in the intensity of daily precipitation over the twentieth century in the United States. Frontal activity is the dominant weather phenomenon in Texas during the winter months, especially for those stations in the northern reaches of the state. There were no changes in winter precipitation intensity for stations in the south and western regions of the state.

Overall, an increase or decrease of trends in precipitation, precipitation days, and precipitation intensity was most notable for selected stations in the eastern half of the state. However, of the 630 hypothesis tested in this study, only 63 trends were detected. Approximately $90 \%$ of the stations resulted in no change in precipitation, days with precipitation, or precipitation intensity.

In general, variability of precipitation was higher for stations in west Texas annually and for all seasons during the period of record. The NA monsoon, convective activity, and the local topography contribute to the high variability in precipitation for stations in this region. Arid environments are subject to short pulses of precipitation over time and space.

An east-to-west trend in precipitation exists due to the distribution of moisture. A day with a probability of precipitation was consistently higher for stations in the east annually and seasonally. These stations receive convective storms, frontal precipitation during the spring and fall months, and are subjected to tropical activity from the Gulf of Mexico during the summer and fall months. For stations in west Texas, the probability of
a day with precipitation was highest during the summer months when compared to other seasons and annually. This is most likely associated with the monsoonal rains and convective activity common in the summer months to stations in this region.

## Limitations

Trend analysis of climate data is complicated by missing data. It is imperative that extensive quality control procedures are employed to ensure that only the most complete and reliable precipitation data sets are used. It may be difficult to replicate this study in other regions of the world simply because good quality data are not available for many regions internationally (New et al. 2001). Long-term reliable operational practices to collect and measure precipitation would greatly improve the trends derived from the observational record. The data sets used for this analysis had missing data and to overcome this issue, this study estimated missing values of monthly and precipitation day data on the 42 stations using regression analysis. Additionally, the USHCN only had data on 42 stations for the state, and as a consequence, many areas around the state such as the northwest Panhandle and the Edwards Plateau were underrepresented spatially and could not be analyzed in this study.

## Future Research

The spatial and temporal patterns of precipitation were a primary focus of my dissertation research. The United States Historical Climatology Network offers precipitation data for 50 states. The methods used in this analysis could be extended to other regions within the United States.

In this dissertation, I focused on the trends in precipitation that occurred over a course of 70 years. One of the results showed an increase in annual, summer, and winter
precipitation intensity for selected stations around the state. It would be interesting to compare those stations and determine if any extreme precipitation event such as those related to hurricanes or heavy thunderstorms was the cause during the period of record. Furthermore, I would like extend this study and compare the extreme precipitation trends and events to the synoptic causes during the period of record. For the second half of the twentieth century, data are available which would allow a more refined analysis; however, earlier periods may be difficult to construct as I may have to rely on the surface observational record (Sheridan 2002). Furthermore, such a synoptic climatology may need to be expanded to cover the Gulf of Mexico and central portions of the United States. I would also like to research extreme precipitation patterns in Texas because an increase of heavy precipitation events has serious ramifications for flood control and water resource management. Reliable and accurate knowledge of flood climatology is vital because it plays a role in many policy decisions. I would also like to investigate total precipitation and extreme precipitation patterns with regards to El Niño and La Niña events.

Another variable to be considered in this research is temperature. In general, as temperatures increase, evaporation rates also increase which leads to more precipitation (Solomon et al. 2007). Investigating temperatures in Texas as it relates to precipitation trends would generate another interesting dynamic to studying climate change on a regional level. Furthermore, I would like to study temperature and precipitation trends and its relationship to extreme precipitation events such as hurricanes that have affected Texas.

## VITA

Rebecca K. Parylak was born in Reno, Nevada to John Edward and Marilyn Burns Parylak on April 5, 1962. Rebecca grew up in San Antonio, TX where she attended Texas State University-San Marcos. After earning her bachelor's degree in Physical Geography in 2000, Rebecca returned to Texas State in 2001 to pursue her Master's degree in Applied Geography. Upon completion of her Master's degree in 2004, Rebecca entered the doctoral program at Texas State and researched precipitation trends.
